Photoelectrochemical behaviour of photoanodes under high photon fluxes†

Isaac Holmes-Gentle,  ‡ Franky E. Bedoya-Lora,  ‡ Lorenzo Aimone and Sophia Haussener  *

The experimental behaviour of photoelectrochemical materials illuminated under high irradiance conditions $>100 \text{ kW m}^{-2}$ has not been studied despite being potentially advantageous for improving the photoelectrochemical performance and the system-level design through the miniaturisation of PEC cells, and for providing conditions that can mimic accelerated ageing or long term operation. This study presents the design of a high flux photoelectrochemical (HFPEC) test cell, which ensured adequate cooling through forced convection, and experimental setup in a high flux solar simulator for the study of light-dependent behaviour of two reference materials, Sn-doped Fe_2O_3 and BiVO_4 , under high irradiances (up to 358 kW m^{-2}). Current densities of up to 1500 and 300 A m^{-2} were achieved for $\text{FTO|Fe}_2\text{O}_3$ and FTO|BiVO_4 , respectively. To qualitatively deconvolve the different phenomena and their effects, temperature dependence studies under approx. 1 sun ($1 \text{ sun} = 1 \text{ kW m}^{-2}$) illumination were performed. It was found that the sublinear light-dependent behaviour was not explained by the temperature increase under illumination and, based on multiphysics modelling, likely primarily arises from bubble-induced losses. Furthermore, whilst the overall degradation rate increases for FTO|BiVO_4 samples under increasing irradiance, a fitted phenomenological model indicates that the degradation kinetics are light-dependent, where increased irradiance diminishes the fraction of charge consumed by photocorrosion reactions. This study highlights the potential of HFPEC experiments to contribute to the scientific analysis of semiconductor–electrolyte behaviour at high photon flux conditions and to identify and resolve the practical challenges of engineering HFPEC devices.

1 Introduction

Photoelectrochemical (PEC) water splitting is seen as a potential sustainable pathway to solar-derived fuels.¹ PEC devices typically consist of at least one semiconductor and an electrolyte, with a direct semiconductor–electrolyte junction. There have been only a few experimental reports of PEC water splitting devices, that include a semiconductor–electrolyte junction, under high solar irradiance. Whilst this experimental space remains understudied, it is of significant interest from both a scientific perspective and an engineering one. Firstly, although the behaviour of solid-state photo-voltaic junctions are well-studied in the established field of concentrated photovoltaics (CPV), there is a knowledge gap in the equivalent field of concentrated photoelectrochemistry. Secondly, solar concentration could be a promising route to increase the current density and miniaturise the device, which could

conceivably improve the economic feasibility.^{1–3} Furthermore, high solar concentration could permit the thermal absorbed energy to be extracted at high temperatures and thereby utilised.

The earliest PEC cell under any appreciable solar concentration was reported in 1998 where Khaselev and Turner achieved a 12.4% solar-to-hydrogen efficiency using a p-GaInP₂ photocathode integrated with a GaAs p–n junction in a monolith at 12 suns ($1 \text{ sun} = 1 \text{ kW m}^{-2}$).⁴ Ten years later, Wang *et al.* achieved unassisted water splitting by coupling a Fe_2O_3 or WO_3 photoanode and a p-GaInP₂ photocathode under 10 suns, although with very small currents (below $20 \mu\text{A cm}^{-2}$ at 10 suns).⁵ Wang *et al.* also investigated the effect of light intensity on photoelectrochemical properties and that the short-circuit photocurrent dependence on light intensity was nonlinear and was affected by photoanode illumination orientation. More recently, there has been a renewed interest in irradiance-dependence studies, but still limited to relatively low solar concentrations (<30 suns). Segev *et al.*⁶ and Gupta *et al.*⁷ performed comprehensive analysis of the performance of various doped Fe_2O_3 films up to 25 suns and LaFeO_3 up to 18 suns, respectively. Both studies reported three-electrode experiments, which isolates the individual behaviour of the photoelectrode,

‡ These authors contributed equally to this work.

and found that the photocurrent at maximum power point (where the photocurrent and photovoltage was defined as the difference between light and dark for current and applied potential, respectively)⁸ was found to increase linearly with flux concentration, whereas the photovoltage at maximum power point was found to increase logarithmically. Shaner *et al.*⁹ showed improved performance at 12 suns of core-shell type Si|WO₃ micro-wires based photoelectrode originating from the improved photovoltage, resulting in improved current-matching. In the present work, the term photovoltage will be used to refer to the separation of quasi-Fermi levels under illumination,^{10,11} rather than the voltage difference between light and dark at a given current.

There has been a number of photoelectrochemical reactor designs which consider solar concentration. Ong *et al.*¹² designed and modelled a PEC reactor design with a sample area of ca. 6 cm² and tested up to 3.5 suns using a Fresnel lens and solar simulator. Vilanova *et al.*¹³ achieved unassisted water splitting by coupling a photovoltaic module (Si) to a photoelectrochemical junction (Fe₂O₃) in a flow reactor designed for low solar concentrations (<17 kW m⁻²). This design was then scaled to an active area of 200 cm² and demonstrated continuous operation under concentrated natural sunlight (~12.8 kW m⁻²) over 4 days (ca. 23 operational hours).¹⁴ Logarithmic saturation behaviour of the photocurrent with increasing solar concentration was observed, which was attributed to bulk recombination losses and substrate ohmic losses, an effect that has also been found in BiVO₄ photoelectrodes.¹⁵ The real-world operating considerations of the PEC-PV reactor design from Vilanova *et al.*^{13,14} were theoretically studied for various solar tracking optical designs, and it was shown that a limited maximum device tilt angle (which is potentially required for efficient bubble removal) could lead to a reduced daily system performance.¹⁶ Along with our previous modelling work on high flux PEC cells,¹⁷ this demonstrates that bubble removal and gas separation must be considered in the early stages of reactor design and when interpreting the experimental results.

In comparison, more studies have been done on integrated PV-EC devices, sometimes referred to as photo-electrochemical devices based on their high degree of integration, under high photon flux. This solar-fuel device architecture has arguable demonstrated higher efficiencies^{18–20} and pilot-scale systems^{21–23} under significant solar concentrations (>400 kW m⁻²).^{20,21} Notably, in a number of these devices the water has dual functionality: acting as a coolant for the PV and reactant for the EC.^{20,22,24–26} Similarly, all high flux PEC cells that continuously operate with a flowing electrolyte could inherently take advantage of this cooling effect of the photoabsorber.

One of the main challenges of performing water splitting under high irradiances is the increased temperature at the photoelectrode surface resulting from the increased photon flux density and correspondingly larger thermal losses. In order to understand and decouple the effects of high irradiances and high temperatures, it is important to study the behaviour of photoelectrodes at different temperatures under 1 sun illumination. Experimentally, this can be achieved by using a PEC test cell immersed in a temperature-controlled water bath or using

a flow cell with external electrolyte heating (or cooling). Regarding hematite photoelectrodes, only a few reports have discussed the temperature-dependence behaviour, with the consensus being that high temperatures (up to 65 °C) promote higher saturation currents, while onset potentials shifts towards positive values,²⁷ causing the current-potential (*JV*) curves to have a steeper S-shape. A recent systematic study associates the increased saturated current with band gap shrinkage and increased carrier concentration, allowing more photons to be effectively converted to charge carriers.²⁸ The delayed onset potential for the photocurrent has been linked to increased flat band potentials for non-doped hematite photoanodes.²⁸ Although an opposite effect has been found for Si-doped hematite, where the onset potential was found to shift towards lower values.²⁹ Similarly, a few studies have reported the performance of BiVO₄ at increased temperatures (between 10 and 85 °C). For this case, saturated currents were also found to increase with temperature,^{30–32} possibly due to suppressed recombination rates in the bulk of the semiconductor due to increased carrier mobility.³⁰ Analogous temperature-dependence studies have been published for other metal oxide photoelectrodes, including CuWO₄,³³ TiO₂ and SrTiO₃,³⁴ reporting similar findings. Nevertheless, there is still a lack of consensus on the origin of temperature-dependent behaviour of photoelectrode materials; even studies on similar materials have reached contradicting findings. These disparities might be due to the diverse routes of synthesis, doping, layer architecture, morphology of the photoelectrode materials, and also experimental setup.

As summarised in Fig. S1 in the ESI,[†] there is a fundamental lack of experimental reports on the behaviour of photoelectrochemical materials at high light intensities. We seek to address this deficit in this work in order to further our physical understanding of these materials under high irradiance. Building upon our previous simulation work,¹⁷ we describe the design of a high flux photoelectrochemical (HFPEC) test cell and the experimental setup in a High Flux Solar Simulator (HFSS) for the study of photoelectrochemical phenomena. In this work, we present the light-dependent behaviour of Sn-doped Fe₂O₃ and BiVO₄ photoelectrodes in the range of 40 to 360 kW m⁻²; and as a complement, we also performed temperature dependence studies between room temperature and 55 °C under 1 sun illumination with the aim of decoupling the effect of high irradiance and temperature.

2 Design of high flux photoelectrochemical cell and experimental setup

There are multiple design challenges for the PEC test cell that are imposed by high irradiances. Firstly, solar concentration leads to higher current densities at the surface of the photoelectrodes. This can lead to increased losses induced by bubble formation through increased light scattering, blockage of electrochemical surface by adherent bubbles (*i.e.* reactant mass transport limitations) and a reduction in the effective electrolyte

resistance. This issue has been noted in previous work,^{4,6} where Khaselev and Turner go as far as to hypothesise that PEC systems may be limited in practical solar concentration to 10 to 20 suns due the aforementioned issue with bubble formation.⁴ High photon fluxes can also exacerbate current density maldistribution which leads to parts of the electrochemically active area to be underutilised. Furthermore, increased currents will lead to larger ohmic losses in the electrolyte and current collector (*e.g.* substrate).

Consequently, operation at high irradiances ($>100 \text{ kW m}^{-2}$) above the historically investigated range ($<30 \text{ kW m}^{-2}$) will require a novel cell design and experimental setup. As discussed in our previous simulation work,¹⁷ the challenges associated with an increased rate of bubble formation can be partially mitigated through removal by high fluid velocities. Similarly, adequate heat transfer from photoelectrode to electrolyte will be achieved by using high fluid velocities over both the front and back surfaces of the photoelectrode. This heat removal through forced convection will also help minimise the effects of temperature on the photoelectrochemical behaviour. The ohmic resistance will be reduced by minimising the distance between electrodes and the use of high-conductivity substrates along with a reference electrode coupled to a Luggin capillary, which should be placed close (within a few millimetres) to the illuminated photoactive area. In this work, two photoelectrode substrates were used, namely, fluorine-doped tin oxide (FTO) glass slides and pure titanium, which enabled the effect of different substrate ohmic losses to be investigated. Furthermore, the sample area was minimised to reduce issues with current density distributions and other scaling effects, as previously observed by Ahmet *et al.*³⁵ Finally, due to the high temperature limitations of the fluoropolymers commonly used for the construction of PEC cells, the cell was machined from stainless steel (316 grade). Whilst our previous simulations¹⁷ show no dangerous hotspots within the reactor, it was prudent to use a material robust enough to ensure that no issues would occur due to light misalignment.

The final reactor design for the HFPEC cell is presented in Fig. 1(A) and (B), and was validated *in silico* using a multiphysics

modelling described elsewhere.¹⁷ The reactor is composed of two end plates with accompanying gaskets that sandwich the sample creating two cavities in which electrolyte can flow on the front and back sides of the sample. Fluidic routing ensures that bubbles are removed by both bubble buoyancy and forced convection (*i.e.* flow direction against gravity on the front and back sides). The HFPEC cell is then assembled within the experimental setup shown in Fig. 1(C) which comprises of an adjustable position optical table for alignment of the HFPEC cell relative to the lamp (and therefore changing irradiances), a water-cooled aperture which defines the illuminated sample area, and a water-cooled shield for absorbing stray illumination which protects the nonilluminated components of the experimental setup.

3 Methodology

3.1 Photoelectrode synthesis and preparation

Three types of photoelectrodes were fabricated *via* spray pyrolysis for testing under high irradiances: (1) Sn-doped Fe_2O_3 deposited on FTO substrate ($\text{FTO}|\text{Fe}_2\text{O}_3$), (2) Sn-doped Fe_2O_3 on titanium foil substrate ($\text{Ti}|\text{Fe}_2\text{O}_3$), and (3) BiVO_4 on FTO/ SnO_2 substrate ($\text{FTO}|\text{SnO}_2|\text{BiVO}_4$). These well-known photoabsorbers were selected as model materials as they have been well-studied under AM1.5G spectrum^{36–38} and have contrasting stability characteristics which allow comparison of the results produced within this study and with previously published literature. Fe_2O_3 and BiVO_4 are known for their relatively high and poor stability respectively, where unmodified Fe_2O_3 (without catalytic layer) is known to perform for over 1000 h without any significant changes in their performance.³⁹ Conversely, unmodified BiVO_4 suffers from instabilities that render the photoelectrode inoperative after only a few hours, although protective and catalytic layers can improve considerably its stability up to 1000 h.⁴⁰ State-of-the-art Fe_2O_3 and BiVO_4 photoelectrodes will employ catalysts (*e.g.*, NiFeO_x ,³⁸ Ru–P,³⁶ Pt³⁷ *etc.*) to enhance the charge transfer efficiency at the semiconductor–electrolyte interface but, in this work, a catalyst deposition step was omitted in order to simplify the photoelectrode synthesis

Fig. 1 An overview of the experimental setup: (A) CAD diagram of the assembled HFPEC cell, (B) CAD diagram of disassembled cell highlighting each layer, and (C) the experimental setup at the high flux solar simulator (HFSS) facility highlighting key components.

methodology and simplify the discussion regarding the mechanism of possible degradation pathways. Spray pyrolysis was used to deposit both films by spraying the precursor solutions onto a heated substrate. For hematite a precursor comprised of 0.1 M $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ (>99%, Acros Organics) and 0.6 mM SnCl_4 (anhydrous, 99%, Thermo Fisher Scientific) in ethanol (99.8% Fisher Chemical) solution was sprayed (20 passes) onto FTO substrates (Solaronix TC22-15, 2 mm) and annealed for 1 h in air at 400 °C.⁴¹ For Ti substrates (99.7% Sigma Aldrich, 0.126 mm), 40 passes were performed with the precursor. For bismuth vanadate photoanodes, 0.1 M SnCl_4 in ethyl acetate was first spray pyrolysed onto FTO substrates to form a thin layer of SnO_2 to improve charge transfer between the substrate and BiVO_4 ; then 8 mM $\text{Bi}(\text{NO}_3)_3$ + 8 mM $\text{VO}(\text{AcAc})_2$ in a solution of acetic acid/ethanol was sprayed and annealed at 450 °C in air for 2 h.⁴² Further details related to the photoelectrode fabrication methods can be found in the ESI in Sections S2.2 and S2.3.† Finally, cyanoacrylate-based glue was painted on the non-illuminated areas of the sample to minimise the dark current contribution.

3.2 Photoelectrochemical testing under high flux light

The photoelectrodes were tested under high irradiances generated from a single lamp at the EPFL high flux solar simulator (HFSS), detailed further in Levêque *et al.*⁴³ The irradiance was characterised by flux distribution mapping of images of a Lambertian target taken by a calibrated IR camera, and a water-cooled calorimeter placed behind the light aperture.^{43,44} Irradiances in the range of 40 and 360 kW m^{-2} were achieved by placing the optical table at different distances from the focal point of the lamp (up to ~ 22 cm). As the light beam is not collimated, beam divergence between the 5 mm diameter aperture and the sample must be taken into consideration. Consequently, the true illuminated area was estimated from the degradation pattern of the BiVO_4 samples. A detailed description of the calibration procedure and results can be found in Section S2.4 of the ESI.† Finally, the spectrum of HFSS light was measured far out of focal point with a UV-vis spectrometer (Ocean Optics) as shown in Fig. S8 of the ESI.†

The HFPEC cell, which was introduced in the previous section, is composed of two stainless steel end plates, two 3 mm thick silicone gaskets, and the photoelectrode. Each end plate has a 2 mm thick quartz window, sealed with an EPDM o-ring and an aluminium retainer ring. Fluidic tubing (PTFE) is connected to the cell *via* PEEK flangeless fittings. Electrolyte (1 M NaOH or 1 M KPi buffer solution, pH 6.6) is circulated using a diaphragm pump with an integrated pulsation dampener (KNF, FP70 KPDCB-4B) at a volumetric flowrate of 3.5 $\text{cm}^3 \text{s}^{-1}$. A potentiostat (Autolab PGSTAT302n) was connected to the HFPEC cell, where the photoelectrode sample was connected as the working electrode, the front reactor stainless steel plate was used as the counter electrode and an external reference electrode (RHE, HydroFlex/Gaskatel) connected to the cell *via* a PTFE/Nafion tube Luggin capillary to ensure that the reference potential was sensed *ca.* 2 mm away from the illuminated surface of the working electrode. Cyclic voltammetry and

chronoamperometry measurements were conducted, and the resulting data were postprocessed to perform ohmic drop compensation (where the uncompensated resistance is determined from EIS measurements at open circuit potential). Further details on ohmic drop compensation can be found in the ESI Section 2.5.† Finally, temperature sensors were placed in the electrolyte reservoir and at the inlet and outlet of the HFPEC. In order to study the thermal performance of the HFPEC further, and with the aim of estimating the temperature at which the photoelectrode operates, a $\text{Ti}|\text{Fe}_2\text{O}_3$ sample was probed with multiple thin-wire thermocouples attached on the back side of the photoelectrode.

3.3 Photoelectrochemical testing at different temperatures

The photoelectrodes were also tested at different temperatures between 24 and 55 °C under 1 sun (AM1.5G) illumination (Trisol Solar Simulator, AOI). The light source spectrum can be found in the ESI in Fig. S8.† A three-electrode flow cell with an exposed/illuminated area of 8 mm in diameter was used to measure the performance of the photoelectrodes. A RHE electrode (RHE, HydroFlex/Gaskatel) and a Pt wire were used as reference and counterelectrode, respectively. A flow rate of 3.5 $\text{cm}^3 \text{s}^{-1}$ was used to ensure conditions similar to those under high irradiances. The electrolyte temperature was controlled by placing a reservoir in a water bath, which was set to different temperatures. Due to heat losses through the pipes, the temperatures were recorded by a thermocouple inside the flow cell a few millimetres away from the exposed area of the photoelectrode.

The PEC properties at different temperatures were measured by voltammetry and chronoamperometry following protocols reported elsewhere.^{45–47} For the photoelectrochemical characterisation of Fe_2O_3 photoelectrodes, voltammograms at 10 mV s^{-1} were performed under dark and illuminated conditions. With the aim of measuring charge transfer efficiencies at the surface, chronoamperometries were performed for 10 seconds in dark and 10 seconds under illumination with a time resolution of 1 μs at different electrode potentials. 1 M NaOH was used as electrolyte for these tests.

In the case of BiVO_4 photoelectrodes, chronoamperometries were performed at 1.23 V *vs.* RHE in 1 M KPi buffer (pH 6.6) for 7 hours under 1 sun illumination at different temperatures. Due to the poor stability of the BiVO_4 samples, a full photoelectrochemical characterisation, similarly to the one performed for Fe_2O_3 samples, was not possible. Instead, the use of this material presents with the possibility of assessing the transient degradation and photocurrent decay observed during the chronoamperometries. Electrochemical impedance spectroscopy was used to measure the ohmic resistance, which was then used to perform chronoamperometries with *iR* compensation.

3.4 Optical and morphological characterisation

The absorbance spectra of the samples (Fe_2O_3 and BiVO_4) can be found in Fig. S14 and S15 in the ESI,† and were measured using a UV-vis spectrometer (UV-2600 Shimadzu) with an

integrating sphere (ISR-2600PLUS Shimadzu). The direct band gaps were 2.19, 2.16 and 2.58 eV for Fe_2O_3 (20 passes), Fe_2O_3 (40 passes), and BiVO_4 , respectively, in agreement with previous reports for both materials.^{41,48} SEM images were performed for pristine Fe_2O_3 and BiVO_4 , as shown in Fig. S10 and S11 in the ESI.† Postmortem images were also taken for BiVO_4 photoelectrodes after experiments under high irradiances, images are shown in Fig. S12.† EDX analysis (Gemini II, Zeiss) was performed on BiVO_4 photoelectrodes before and after experiments, detailed results are shown in Fig. S13.†

4 Results and discussion

4.1 Thermal performance of the HFPEC cell

In order to study the thermal behaviour of the HFPEC test cell, multiple thermocouples were attached to the back of a sample with a titanium foil substrate and three resistance temperature sensors measured the electrolyte temperature at the inlet and outlet of both sides of the cell. The electrolyte volumetric flow was kept constant for all experiments ($3.5 \text{ cm}^3 \text{ s}^{-1}$). Shown in Fig. 2(A), the recorded temperature of the sample understandably increased under increasing irradiation, where the thermocouple placed directly in the centre of the illuminated area reached *ca.* $54 \text{ }^\circ\text{C}$ at 358.5 kW m^{-2} . The experimental results showed close agreement with simulations (model outlined in ref. 17), and it is hypothesised that the under-prediction of the model at higher light powers could be attributed to the method of thermocouple attachment inherently leading to increased

thermal insulation of the backside of the thermocouple to the fluid flow in the rear chamber of the HFPEC. Regardless, this demonstrates the validity of the cooling strategy and that the HFPEC design is successful in limiting the temperatures to safe levels. Furthermore, as the electrolyte is recirculated, the electrolyte reservoir temperature was monitored during all experiments and was typically raised from *ca.* 18 to $22 \text{ }^\circ\text{C}$ during all of the experiments outlined in this work, as can be observed in Fig. S17.† The thermal validation presented above serves as confirmation that the model can be used to estimate the surface temperature of the photoelectrodes. Direct temperature measurements on the surface were not possible due to the thermocouples obstructing the incident light. Therefore, the surface temperatures of the photoelectrodes deposited on Ti and FTO were predicted by the thermal model, and can be found in Fig. 2(B). The average predicted surface temperature ranges between 20 and $45 \text{ }^\circ\text{C}$ depending on the irradiance and the type of substrate used.

4.2 Photoelectrochemistry of hematite under high flux

The photoelectrochemical behaviour of $\text{FTO}|\text{Fe}_2\text{O}_3$ and $\text{Ti}|\text{Fe}_2\text{O}_3$ samples under high irradiances was measured and the results shown in Fig. 3. The $\text{FTO}|\text{Fe}_2\text{O}_3$ dataset at 358 kW m^{-2} was affected by considerable experimental noise and a large ohmic drop compensation. Therefore, the results above *ca.* 1.5 V vs. RHE were removed for clarity; the original data is shown in Fig. S18.† At the highest solar irradiance tested (358 kW m^{-2}), the recorded photocurrent densities for both substrates at 1.25 V vs. RHE were between 100 and 200 A m^{-2} vs. without ohmic compensation. Conversely, after ohmic drop compensation (also known as *iR* compensation and described in detail in the ESI, Section S2.5†), $\text{FTO}|\text{Fe}_2\text{O}_3$ significantly outperformed the $\text{Ti}|\text{Fe}_2\text{O}_3$ sample, registering photocurrent densities of $\sim 750 \text{ A m}^{-2}$ vs. at 1.25 V vs. RHE . Given that this is the highest irradiance used for PEC experiments, it is unsurprising that the recorded photocurrent densities demonstrated in this work are significantly larger than previous demonstrations.^{6,13,14}

As it can be seen in Fig. 3(D), the performance of the $\text{Ti}|\text{Fe}_2\text{O}_3$ sample was relatively unaffected by compensating for the series resistance which indicates that the uncompensated resistance in the $\text{FTO}|\text{Fe}_2\text{O}_3$ sample is primarily from the substrate resistance. Whilst this finding was previously reported in Segev *et al.*⁶ for $<30 \text{ kW m}^{-2}$ and Vilanova *et al.*¹⁴ for $<13 \text{ kW m}^{-2}$, the unique high irradiance experimental conditions in this work mean that the full asymptotic behaviour is seen (*cf.* Fig. 3(C) dotted lines), which demonstrate the severe unsuitability of unmodified FTO for such photoelectrodes at high solar concentrations ($>100 \text{ kW m}^{-2}$). Nevertheless, the conductivity of FTO substrates could be improved through the deposition of conductive metal busbars,^{35,49} potentially permitting the use of FTO under high flux conditions.

For both photoelectrochemical and photovoltaic junctions, the current generated from absorbed photons is hypothetically linearly proportional to irradiance^{50,51} and from a number of first-principles derivations,^{52–54} it is possible to derive an analytical equation for the charge transfer of minority carriers

Fig. 2 (A) Temperature at the back of Ti substrate at different irradiances. Values were taken in steady state condition (after 10 minutes of illumination). Dashed lines show the predicted temperatures, the model used for these predictions has been described in a previous publication.¹⁷ (B) Predictions of the average surface temperature as a function of irradiance obtained using the same model.

Fig. 3 Photoelectrochemical performance of FTO|Fe₂O₃ and Ti|Fe₂O₃ under high fluxes. The photocurrent normalised by the irradiance of (A) FTO|Fe₂O₃ and (B) Ti|Sn–Fe₂O₃ shows how the shape of the characteristic photocurrent response changes with varying irradiance. The inset figure in (A) and (B) shows the respective photocurrent density vs. irradiance. The irradiance dependence of photocurrent densities for selected potentials (1.00, 1.25, 1.50 V vs. RHE) with and without ohmic drop compensation is shown for (C) FTO|Fe₂O₃ and (D) Ti|Fe₂O₃.

(holes) in photoanodes. For an ideal photoanode under high enough reverse bias, the measured current will primarily be the photogenerated current and any recombination in the space-charge region will be minimised, and therefore a simplified Gärtner–Butler equation can be used (eqn (1)). Assuming that the term $j_0 = eD_p p_0 / L_p$ is small relative to the 2nd term in eqn (1) (which is a good approximation under 1 sun illumination for hematite⁵⁵), the ideal total current density j_{total} should be proportional to the light intensity I_0 , assuming that the absorption coefficient α , the thickness of space charge region W_{SCR} and the diffusion length of holes L_p are independent of I_0 . However, it is very important to highlight that this proportionality relation is only valid under relatively low injection conditions for an ideal photoelectrode and will not necessarily hold under high injection conditions found at high irradiances studied in this work. Nevertheless, the experimental results will be compared with this ideal linear dependence.

$$j_{\text{total}} \approx j_{\text{GB}}, \quad j_{\text{GB}} = j_0 + eI_0 \left(1 - \frac{\exp(-\alpha W_{\text{SCR}})}{1 + \alpha L_p} \right) \quad (1)$$

Fig. 3 show that when iR compensation is taken into consideration, the photocurrent density scales sub-linearly with irradiance. For example, for FTO|Fe₂O₃ at 1.23 V vs. RHE, the measured normalised photocurrent at 122 kW m⁻² and 358 kW m⁻² is 28% and 36% respectively less that expected from the results at 37.3 kW m⁻². Equivalently for Ti|Fe₂O₃, this is 27% and 36% respectively. Notably, this sub-linear behaviour is maximal at intermediate potentials for FTO|Fe₂O₃ (1.0–1.6 V vs. RHE in Fig. 3(A)) but maximal at highest potentials for Ti|Fe₂O₃ (Fig. 3(B)).

For Fe₂O₃, this approximately linear behaviour of photocurrent densities at relatively low irradiances (*i.e.* <30 kW m⁻²) has been previously observed by a number of authors.^{6,41,56} Vilanova *et al.*¹⁴ observed a non-linear increase in uncompensated photocurrent with increasing solar concentration which can likely be attributed to substrate conductivity, and is broadly similar to the behaviour shown in Fig. 3(C). Notably, a number of researchers used varying monochromatic light under low irradiance (<0.4 kW m⁻²) as a strategy to study the mechanism of charge transfer^{56,57} and observed a non-linear relationship

between the surface hole charge and irradiance. Whilst the exact mechanism is disputed (*i.e.* attributed to both a change in reaction mechanism,^{56,58} light dependence of the water oxidation rate constant,⁵⁹ and band edge unpinning effects⁶⁰), these results demonstrate the complexity in building a detailed model from first principles which unequivocally explains the photoelectrochemical behaviour experimentally observed. Therefore, given the challenges in performing the typical diagnostic experiments required to elucidate mechanism (*e.g.* EIS, transient photocurrent, IMPS, TAS *etc.*) under the high simulated solar flux conditions achieved in this work, we seek to give a more qualitative discussion on the observed photoelectrochemical behaviour under high flux.

As discussed in our previous modelling work,¹⁷ there are a number of photoelectrochemical engineering phenomena that may conceal the fundamental behaviour of the semiconductor–electrolyte interface such as ohmic losses caused by the substrate, electrolyte and bubbles, light scattering by bubbles, and bubble coverage of the electrochemically active area. Furthermore, the temperature of the junction increases with increasing irradiance which will impact various photoelectrochemical properties (*e.g.* recombination rate, kinetics of transfer to the electrolyte *etc.*). In the results presented in Fig. 3, ohmic compensation applied removes the ohmic drop associated with substrate/electrolyte under no illumination, but the bubble ohmic losses will remain (where previous modelling suggests a photocurrent loss of up to 10% (ref. 17)).

In order to qualitatively deconvolve the differing phenomena and their effects, the temperature-dependent photoelectrochemical behaviour of Fe₂O₃ under 1 sun illumination was studied, as an increase in sample temperature was observed with increasing high flux. Shown in Fig. 4, the photocurrent density for both samples initially decreases with increasing temperature at low potentials, and then increases at higher potentials (where the switch in temperature dependent behaviour is observed at *ca.* 1.3 and 1.2 V *vs.* RHE for FTO and Ti substrates). However, the magnitude of this change in the two regions is contrasting, where FTO|Fe₂O₃ shows a larger decrease compared to Ti|Fe₂O₃ for low potentials. Furthermore, at high

potentials, FTO|Fe₂O₃ exhibits only a minor improvement (*ca.* 2% at 1.4 V *vs.* RHE) in the saturated photocurrent whereas it is significantly improved for Ti|Fe₂O₃ (*ca.* 70% at 1.4 V *vs.* RHE). Similar behaviour can be observed in the charge transfer efficiency data (Fig. S21 and S22†) calculated using chronoamperometry.⁴⁶

The difference between FTO|Fe₂O₃ and Ti|Fe₂O₃ samples observed in Fig. 4 can be associated to undesired formation of a TiO₂ layer during the spray pyrolysis (450 °C) on Ti, and posterior thermal treatment (400 °C). Prior the spray, when the substrates were reaching the deposition temperature, a change in colour from grey to blue was observed on the Ti substrates, which is consistent with the formation of TiO₂. This layer might act as a barrier for electron transfer between the hematite film and the Ti substrate,⁴¹ which can introduce a temperature dependence. Unintentional Ti-doping could also contribute to this behaviour, which has been found to have a temperature-dependent behaviour for hematite photoanodes.²⁷

Whilst the temperature dependence of photoelectrodes will be specific to sample composition and preparation, a number of studies have shown similar behaviour,^{27,29,34} albeit with a more significant increase in the saturated photocurrent at high potentials for FTO|Fe₂O₃ samples. By comparison of these results with the experiments under high irradiances, the general decrease in the normalised photocurrent cannot be wholly explained by the effects of temperature. This is most apparent for Ti|Fe₂O₃ where opposite trends were observed: a decrease in photocurrent with irradiance *vs.* an increase in photocurrent with temperature for >1.2 V *vs.* RHE. Therefore, based on our previous numerical simulation which extrapolated photoanode behaviour from 1 sun experiments,¹⁷ it is expected that a significant proportion of the observed decrease is caused by bubble losses. However, it remains likely that there is fundamental irradiance-dependent phenomena of the semiconductor–electrolyte junction (*e.g.* bandgap, reaction kinetics, space charge layer thickness *etc.*) which cannot be easily deconvoluted from the engineering phenomena, without further challenging diagnostic experiments (*e.g.* EIS, IMPS *etc.*).

Fig. 4 Temperature dependence of voltammograms for (A) FTO|Fe₂O₃ and (B) Ti|Fe₂O₃. Further details are found in the ESI in Fig. S21 and S22.†

Previous studies have indicated that photovoltage improves with increasing solar concentration for various PEC systems.^{6,7,9} The onset potential, as defined in Section S2.6 in the ESI,[†] is plotted in Fig. 5 and displays a similar trend. The calculated gradient of -150 mV per decade for FTO|Fe₂O₃ and -192 mV per decade for Ti|Fe₂O₃ is comparable to that measured previously,⁶ and, as highlighted by Segev *et al.*, is significantly higher than the open-circuit voltage of state-of-the-art CPV cells.⁶ This further highlights the potential benefit of solar concentration for PEC photoanode materials. This logarithmic dependence on irradiance is observed over the entire range (38 – 358 kW m⁻²) for FTO|Fe₂O₃ but only up to 173 kW m⁻² for Ti|Fe₂O₃ where it is asymptotic towards ~ 0.79 V vs. RHE. The mechanism responsible for this dissimilar behaviour is likely non-trivial and requires further study to account for the temperature effect. One diagnostic technique that could be used to probe PEC samples is photoelectrochemical impedance spectroscopy (PEIS) and this was attempted under high irradiances, but resulted in noisy spectra due to the significant rate of bubble formation. However, these time-consuming experiments did demonstrate the temporal-stability of Fe₂O₃ samples through the similarity of photoelectrochemical behaviour before and after multiple experiments (shown in Fig. S20[†]).

A number of mitigation strategies could be employed to reduce the bubble losses further,⁶¹ and we suggest that the bubble concentration could be further decreased through the optimisation of our HFPEC flow reactor design to further maximise electrolyte velocity across the photoelectrochemically active area. Alternative methods include the use of surfactants, magnetic and acoustic fields,⁶² although their suitability for high flux PEC systems remains to be tested. Furthermore, to study the fundamental behaviour of the semiconductor–electrolyte junction under high irradiances, a potentially instructive research direction would be into developing and performing the challenging diagnostic experiments, such as PEIS, transient photocurrent and intensity-modulated photocurrent

spectroscopy (IMPS), under >100 kW m⁻² illumination from a high flux solar simulator.

4.3 Photoelectrochemistry of bismuth vanadate under high flux

BiVO₄ films of 170 nm thickness were spray pyrolysed on FTO substrates previously coated with a film of SnO₂ of *ca.* 200 nm, as shown in the SEM images in the ESI, Fig. S10 and S11.[†] The SnO₂ layer was necessary to improve the hole transfer by acting as a hole barrier and preventing recombination at the FTO|BiVO₄ interface,¹⁵ additionally it improved the homogeneity of the films during the spray deposition. With the aim of studying the degradation processes occurring at high photon fluxes, FTO|BiVO₄ samples were exposed at different irradiances and currents were measured at an applied potential of 1.23 V vs. RHE (after *iR* compensation) in 1 M KP, pH = 6.6. Chronoamperometries in Fig. 6(A) show the transient current densities at different irradiances; as expected, higher current densities were observed at higher irradiances, although with faster current decay. Fig. 6(B) shows the same set of data with current densities normalised by irradiance. It is evident that during the initial stages (<20 seconds) higher irradiance-normalised currents are obtained at *ca.* 120 kW m⁻² (see inset of Fig. 6(B)). For example, after 20 seconds of illumination at 85 kW m⁻² a normalised current density of 1.02 A kW⁻¹ was achieved, while at 122 kW m⁻² it was 1.33 A kW⁻¹, meaning a 30% increase in normalised-irradiance current. This is an indication of possible optimal conditions for water splitting at high irradiances when opposing effects influence the photocurrent densities. Similarly to the behaviour observed for Fe₂O₃ samples, among these effects we can consider the favourable improved kinetics and decreased thermodynamic requirements due to increased surface temperature, enhanced electron conductivity in the bulk of BiVO₄,³² and thermally activated minority carrier transport,³⁰ but also unfavourable light scattering, increased ohmic drop and surface coverage due to bubble evolution,¹⁷ and increased recombination rates in the bulk due to saturation of band edges with charge carriers at high photon fluxes.¹⁵

The increase in photocurrent density decay expressed as $\partial j/\partial t$, shown in Fig. 6(C), is evidence of increased degradation rates with increased irradiances. Fig. 6(D) shows the current density at 60 seconds and the maximum current density decay for each irradiance (after the initial 20-second peaks). The influence of the aforementioned competing effects are evidenced by the non-linearity of both curves in Fig. 6(D). Although, the chronoamperometries were performed with ohmic drop compensation, the effect of bubbles at higher current densities was not corrected for, and it is estimated to be a contributor for the decrease of photocurrent densities at higher irradiances, in a similar manner as found for Fe₂O₃ samples in the previous section.

The loss of the BiVO₄ film was monitored by postmortem SEM imaging after irradiation for 28 minutes. As shown in Fig. 6(B), the samples irradiated up to 85.3 kW m⁻² still exhibited significant photoactivity after 28 minutes, this was confirmed by the presence of BiVO₄ film on the substrate. For

Fig. 5 Onset potential vs. irradiance for FTO|Fe₂O₃ and Ti|Fe₂O₃ and the linear fit. For Ti|Fe₂O₃, only the range 38–173 kW m⁻² are fitted.

Fig. 6 (A) Chronoamperometry of FTO|BiVO₄ at 1.23 V vs. RHE and different irradiances, inset shows the SEM images for the pristine sample and postmortem for selected irradiances, the full set of SEM images can be found in the ESI† (B) Current densities normalised by irradiance, inset shows the first 60 s after illumination. (C) Derivative of current density vs. time. (D) Current density at 60 s, and maximum derivative of current density vs. time as a function of irradiance. For the calculation of the maximum derivative, the first 20 s after illumination were not considered because the fast decay during this 20 s-period is associated to fast processes not related to photocorrosion.

irradiance >173 kW m⁻², no film was observed on the substrates, as seen in the inset of Fig. 6(A). Remarkably, for exposures higher than 290 kW m⁻², spherical deposits of ca. 200 nm in diameter were observed after high irradiance exposure. EDX analysis (Fig. S13 in the ESI†) showed that these deposits are rich in Bi and P, possibly related to the re-deposition of dissolved Bi present in the phosphate electrolyte or the formation of a more stable Bi-rich phase. This suggests that the mechanism of BiVO₄ at lower irradiances follows the dissolution process proposed by Toma *et al.*⁶³ with dissolution of both metal ions, Bi and V, and without formation of a thermodynamically stable Bi oxide layer. However, at higher irradiances, the formation of Bi-rich phases could occur due to increased surface temperatures, allowing structural rearrangement of V-deficient phases to form, for example, Bi oxides.⁶³ Additionally, a white residue was observed on the samples subjected to irradiances >290 kW m⁻², which can be attributed to the Bi-rich spherical particles observed in the SEM images. Moreover, the Bi-rich particles were absent on the edges of the exposed area, this suggests the effect of current density distributions (*i.e.* heterogeneity in current density). Higher current densities have been predicted for the edges of the electroactive area relative to the centre of the sample,¹⁷ promoting a decrease in local pH and thermodynamically hindering the formation of

Bi oxide, as suggested by the *E*-pH diagram for the Bi-V system in aqueous solution.⁶³

It should be mentioned that the stable photocurrent densities observed for lower irradiances (<37.3 kW m⁻²) are not an indication of film stability. Chronoamperometries shown in Fig. 6(A) are in agreement with the measurements by Zhang *et al.*,⁶⁴ who also found that dissolution occurs even during the early stages of 'stable' photocurrent densities. This is because the instant film thickness is still thicker than the hole diffusion length at the early stages of degradation.

In the case of completely dissolved films (for irradiances >173 kW m⁻²), small and stable photocurrent densities (*ca.* 10% of the initial photocurrent) were still observed after *ca.* 1000 seconds, as seen in Fig. 6(B). These small photocurrents could be attributed to remnant BiVO₄ protrusions still present on the substrate after dissolution of the film. These sparse protrusions were observed in pristine samples and samples subjected to 10 h of continuous water splitting under 1 sun at 1.23 V vs. RHE, SEM images of these defects can be found in Fig. S23.†

The present consensus for the BiVO₄ degradation process is a dissolution mechanism as reported by Toma *et al.*⁶³ and Siyuan Zhang *et al.*⁶⁴ Liming Zhang *et al.* reported the effect of temperature on the performance of nanostructured BiVO₄ and how the size of the particles impact the photocurrent densities

regarding the relation between their size, the depletion layer and the minority diffuse region thickness.³⁰ This dissolution mechanism was confirmed by the SEM/EDX analysis observed for our BiVO₄ samples (Fig. S12 and S13†). Using these reports as a basis, a phenomenological model is proposed below for the transient dissolution of BiVO₄ under high irradiances. The assumptions for the model and a more detail description can be found in the ESI in Section S3.7.† Due to the film thickness decreasing with time, the Gärtner–Butler relationship was defined as a piecewise-defined function depending on the relationships between the instantaneous film thickness (L_{film}), the diffusion length of holes (L_p) and the space charge region thickness (W_{SCR}), expressed as follows:

$$j_{\text{GB}} = \begin{cases} eI_0 \left(1 - \frac{\exp(-\alpha W_{\text{SCR}})}{1 + \alpha L_p} \right) & L_{\text{film}} > L_p \\ eI_0 \left(1 - \frac{\exp(-\alpha W_{\text{SCR}})}{1 + \alpha L_{\text{film}}} \right) & W_{\text{SCR}} \leq L_{\text{film}} \leq L_p \\ eI_0 \left(1 - \frac{\exp(-\alpha L_{\text{film}})}{1 + \alpha L_{\text{film}}} \right) & L_{\text{film}} < W_{\text{SCR}} \end{cases} \quad (2)$$

where W_{SCR} can be expressed as a function of:

$$W_{\text{SCR}} = \left(\frac{2\varepsilon_r \varepsilon_0}{eN_D} (E - E_{\text{fb}}) \right)^{1/2} \quad (3)$$

where α is the average absorptivity, e is the elementary charge, I_0 is the incident photon intensity, ε_r is the relative permittivity of the film, ε_0 is the vacuum permittivity, N_D is the donor density, E is the applied potential and E_{fb} is the flat band potential. Due to the challenging task of dissociating the effect of temperature on N_D , ε_r and E_{fb} separately, the fitting of all these parameters was merged into W_{SCR} .

Assuming two-electron transfer for the dissolution of BiVO₄ and that the formation of a passivating film is kinetically hindered,⁶³ the instantaneous corrosion rate can be estimated as:

$$\text{CR} = \Phi_{\text{deg}} \times \frac{j_{\text{GB}} M}{2F\rho} = -\frac{\Delta L_{\text{film}}}{\Delta t} \quad (4)$$

where Δt is the time between the current measurements (1 s), M and ρ are the molecular weight and volumetric mass density of BiVO₄, and Φ_{deg} is the dissolution fraction, *i.e.*, the fraction of charge involved in the dissolution process. The corrosion rate (CR) has units of [length] [time]⁻¹ and can be used to estimate the decrease in film thickness after Δt has passed.

The contribution to the photocurrent due to BiVO₄ protrusions and other defects on the film, which dissolved at considerably slower rates, was assumed constant and equivalent to the current density measured at the end of the experiment. Therefore, the total current density can be estimated as $j_{\text{total}} = j_{\text{stable}} + j_{\text{GB}}$, where j_{stable} was experimentally measured as the average photocurrent density in the last 10 seconds of illumination. The contribution of dark current densities was negligible, as was confirmed experimentally. The predicted film thickness history of the BiVO₄ films and instantaneous dissolution rates (CR) at different irradiances and temperatures

(under 1 sun illumination) are shown in the ESI in Fig. S26(C) and (D).†

The piecewise function described above allows for the prediction of the photocurrent at the different stages of degradation. In the case of transient experiments under high irradiances, four regions were observed as shown in Fig. S24:† (1) capacitive region and other fast transfer phenomena (recombination kinetics), (2) dissolution for the case $W_{\text{SCR}} \leq L_{\text{film}} \leq L_p$, (3) dissolution when $L_{\text{film}} < W_{\text{SCR}}$, and (4) stable photocurrent due to residual BiVO₄. The fitting of this model to chronoamperometries obtained at low irradiances (37.3 and 85.3 kW m⁻²) was not possible due to absence of the last two regions in the experimental data. In order to extract useful information from the chronoamperometries, three parameters were fitted to the transient photocurrent densities for regions (2) and (3): the dissolution fraction (Φ_{deg}), the space charge region width (W_{SCR}) and the diffusion length (L_p).

In the case of the experiments performed under 1 sun at different temperatures, 5 regions were observed as shown in Fig. S25:† (1) capacitive region and other fast phenomena, (2) dissolution for the case $L_{\text{film}} > L_p$, (3) dissolution for $W_{\text{SCR}} \leq L_{\text{film}} \leq L_p$, (4) dissolution when $L_{\text{film}} < W_{\text{SCR}}$, and (5) stable photocurrent due to residual BiVO₄. For this case, four parameters were fitted to the transient photocurrent densities for regions (2), (3) and (4): the dissolution fraction (Φ_{deg}), the space charge region width (W_{SCR}), the diffusion length (L_p) and the absorptivity (α).

The fittings to the model for the two cases, high irradiances and high temperatures, can be seen in Fig. 7(A) and (B), respectively. The confidence interval (95%) for the fitted parameters is very narrow, *ca.* 2% of the values, as shown by the error bars in Fig. 7(C) and (D), as well for the rest of fitted parameters as shown in Fig. S26.† For high irradiances (>122 kW m⁻²), the region at which $L_{\text{film}} > L_p$ seems to occur too fast to be observable on the chronoamperometries, this could be explained by the fast dissolution of BiVO₄ in the first stages when the current density is the highest. The fitted space charge region width (W_{SCR}) was found to increase with irradiance (Fig. S26(A)†). As this parameter is a function of different materials parameters that are temperature dependent, see eqn (3), the interpretation of this trend is difficult elucidate. For example, the relative permittivity,^{65,66} donor density and flat-band potential²⁸ are known to increase with temperature for semiconducting materials. Hence, the de-convolution of these parameters is challenging given their relation to the space charge region width. On the other hand, the dissolution fraction was found to decrease with irradiance as seen in Fig. 7(C); at first, this might seem contradictory, as faster degradation rates were observed for higher irradiances. To confirm this effect, the photocurrent density was normalised by irradiance, and the time of measurement was divided by the time at which the current density decay was fastest. Hence, effectively normalising the chronoamperometry curves in the current and time domain. It was found that at higher irradiances the normalised current density decays at a slower rate (see Fig. S28(A)†). This confirms that at higher irradiances the dissolution fraction decreases, although the net degradation

Fig. 7 Results of the model for prediction of BiVO₄ degradation. Experimental and predicted photocurrent densities at (A) different irradiances, 122–358 kW m⁻², and (B) different temperatures 26–48 °C, under 1 sun = 1 kW m⁻². (C) Estimated fraction of current towards degradation via dissolution of BiVO₄ as a function of (C) irradiance and (D) temperature.

rate increases due to increased photocurrent densities. Fitted hole diffusion lengths (L_p) showed a decrease with irradiance between 93 and 65 nm, as observed in Fig. S26(A).[†] For BiVO₄ it has been reported that L_p is in the order of 100 nm,⁶⁷ and it is proportional to the square of the lifetime and mobility of the charge carrier (holes). The decrease of this parameter with irradiance can be explained by the increased recombination caused by hole-saturated valence band and exacerbated by the poor kinetics for oxygen evolution at the surface.

To decouple the effects of temperature from irradiance on the degradation rates, the fitting was also performed on BiVO₄ samples at different temperatures but illuminated under 1 sun (1 kW m⁻²). Fig. 7(B) shows that degradation rates increased with temperature under the same irradiance, which is confirmed by the dissolution fraction as shown in Fig. 7(D). This suggests that the decrease in the dissolution fraction at higher irradiances is not directly related to the higher temperatures at the surface of the photoanode. Instead, it might be due to the high photon fluxes being absorbed by the film. Hence, we expect that operating at high irradiances while keeping the photoelectrode at room or lower temperatures (*e.g.* with active cooling), it could further decrease the dissolution fraction. This assertion was tested by running the fitting while accounting for temperature changes in W_{SCR} and L_d , and recalculating Φ_{deg} . As expected the dissolution factor was lower

when temperature was kept constant, the results can be seen in Fig. S27.[†]

Abdi and van de Krol performed studies at different irradiances (<10 kW m⁻²) for bare BiVO₄ and BiVO₄|CoPi samples, and found that the absorbed photon to current efficiency (APCE) decreased with irradiance for both cases.¹⁵ In the case of bare samples, they associated this behaviour to slow kinetics for oxygen evolution, while high irradiances increased the conductivity of the material (photodoping) caused by accumulation of electrons in the conduction band. This issue could be alleviated by adding a catalyst on the surface, *e.g.* CoPi, although the charge transfer would still be limited by poor electron conductivity at higher irradiances. This behaviour could also be linked to the non-linearity found between irradiance and current density in Fig. 6(D) and the slower rate of dissolution as shown in Fig. 7(C). In contrast, it has been found that for electrodeposited Mo-doped BiVO₄, the onset potential shifts in the positive direction, while saturated current densities increased with temperature following an Arrhenius-type behaviour.³⁰ Similarly, it has been found that at high temperatures (≈ 40 °C), the charge carrier recombination in the bulk was suppressed for non-doped BiVO₄ produced *via* PLD, achieving higher photocurrents at those temperatures.³² Although, a recent study found that for spin-coated non-doped BiVO₄ photoelectrodes, the temperature does not impact its

performance, while V-doped samples exhibited an increased saturation current, higher incident to photon current efficiencies (IPCE) at 85 °C and shifted onset potentials in the cathodic direction.³¹ The disparity among these reports are possibly due to the different types of doping, morphology and architectures used for the fabrication of the photoelectrodes.

Regarding the other three fitted parameters for the temperature-dependence study: W_{SCR} , L_p and α , the results are shown in Fig. S26(B).[†] W_{SCR} was found to increase with temperature, however, in a similar manner to the irradiance-dependence study, it is difficult to establish the origin of this trend due to the convoluted effects associated to this parameter. In the case of L_p , it increased slightly from 80 to 90 nm with temperature from 26 to 48 °C. This effect might be related to increased diffusion coefficients and mobilities of holes with temperature. For α , an overall decrease was observed with temperature but with a weak correlation, this might be due to the weak dependence of absorbance with temperature. To date, no study on the temperature dependence of absorbance, or absorptivity, with temperature has been reported for BiVO₄.

As presented above, only a few studies have studied the joint effect of temperature and irradiance on the performance of BiVO₄ photoelectrodes. To elucidate further these inconsistencies, it is critical to study photoelectrode performances under different conditions to effectively de-convolute the effects occurring at high irradiances. For this, it is necessary to characterise the behaviour of photoelectrodes (i) at different temperatures (at constant irradiance), (ii) at higher irradiances with known surface temperature, (iii) and under different conditions to isolate different recombination processes, *e.g.* by using appropriate catalysts or sacrificial reagents. Here, we present the results of the first two approaches for high photon fluxes (>100 kW m⁻²), which have not been reported previously for BiVO₄ photoanodes. In summary, although bulk recombination aggravates with irradiance for BiVO₄, but it is suppressed at high temperatures, the increased surface temperature at higher irradiances could also preferentially enhance the kinetics for oxygen evolution over the dissolution kinetics, specially when the conduction and valence band are saturated with electrons and holes, respectively. This could lead to relative improved stability as shown by the decrease in the dissolution factor and improved performances as observed in the optimal normalised photocurrent achieved at *ca.* 120 kW m⁻².

High irradiance measurements could potentially be used as accelerated tests for degradation of stable BiVO₄. The results presented in this study seem to indicate that at very high irradiances the temperature at the surface and the charge-saturated band edges might change the degradation mechanism and alter the kinetic rates of dissolution and recombination. Hence, these effects must be taken into account when such accelerated degradation tests are formulated and if this approach is used to assess the performance and stability of photoelectrodes.

5 Conclusions

This work reports the study of photoelectrode materials (Fe₂O₃ and BiVO₄) under high irradiances (up to 358 kW m⁻²). For this,

a unique PEC test cell for high flux applications was designed and successfully used to conduct photoelectrochemical experiments with thermal management to keep the photoelectrode samples at suitable temperatures. Current densities of up to 1500 and 300 A m⁻² were achieved for FTO|Fe₂O₃ and FTO|BiVO₄ respectively at 358 kW m⁻². The sublinear behaviour observed for the current densities as a function of irradiance has been attributed to macroscale effects such as excessive bubble formation at the surface, ohmic drop due to poorly conductive substrates, and current density maldistribution.¹⁷ However, it is also possible that competing effects in the semiconducting properties of the material could arise from the increased temperature at the surface. For this, temperature-dependent studies were also performed under low irradiance (AM1.5G, 1 kW m⁻²). It was found that for FTO|Fe₂O₃ samples the effect of temperature is minimal compared to the current density losses at high irradiances. In the case of Ti|Fe₂O₃, it was found that the photocurrent at high bias increases with temperature, which is in contrast with the decrease in performance observed at high irradiances. Whilst the effect of temperature has qualitatively been eliminated as the explanation for the sub-linear irradiance dependence, these losses could be caused by bubbles, as predicted from multiphysics modelling, but also due to changes to the semiconductor properties that are challenging to deconvolve without further study. For FTO|BiVO₄, it was found that at high temperatures the dissolution fraction increases, although an opposite effect was found at high irradiances. Future studies involving *in situ* measurements, *e.g.* IMPS, PEIS, IPCE and ICP-MS, are needed to fully decouple the contribution of temperature and high photon fluxes on the mechanism of photocurrent generation and degradation of photoelectrode materials, this would require the development and modification of the aforementioned techniques to operate under these challenging experimental conditions.

The experimental methodology proposed here would facilitate the study of other semiconducting materials, such as WO₃, LaFeO₃, or Cu₂O under high fluxes, for example with the promise of finding optimal conditions for the irradiance and temperature at which photoelectrode materials could operate for efficient solar-driven water splitting. These optimal conditions are caused by intertwined competing effects: favourable enhanced kinetics and thermodynamic requirements for oxygen evolution, thermally activated mobility carrier transport and electron conductivity; and, unfavourable effects due to excessive bubble evolution, and increased recombination rates in the bulk of the semiconductor under charge carrier saturation of band edges. The results from this study open the possibility of using high photon fluxes as means of accelerated testing for assessing the stability of photoelectrodes. Although care must be taken to confirm that the degradation mechanism has not been altered at high irradiances. Furthermore, this study allows to study fundamental transport phenomena in the materials and provides insight into the engineering design of high flux PEC systems, which would allow the miniaturisation of these devices and the possibility of advantageous thermal integration.
