A sodium ion-selective photosensitizer: dibrominated F-BODIPY as a fluorescence imaging and therapeutic agent

A photosensitizer, a benzo-15-crown-5 functionalized F-BODIPY dye, detects sodium with high selectivity, fast response, and bright, photostable fluorescence. Its signal and singlet oxygen generation are boosted by the elevated sodium levels as e.g. found in malignant cells, enabling precise tumour imaging. Upon light activation, the photosensitizer could selectively kill cancer cells, combining diagnostic power with therapeutic action. This dual functionality positions the photosensitizer as a promising agent for photodynamic cancer therapies.

Herein, we report that the production of singlet oxygen ($^1O_2$) is exclusively regulated by sodium ions in aqueous solution by the use of a Na^+-selective photosensitizer (PS), a 2,6-dibrominated F-BODIPY dye equipped with benzo-15-crown-5. The PS showed an enhanced fluorescence quantum yield (Φ_f) and an enhanced singlet oxygen quantum yield (Φ_Δ) in the presence of Na^+. A detailed theoretical study uncovered the underlying photophysical pathways which are responsible for both functional characteristics of the PS, therapeutic and Na^+ imaging properties.

1. Introduction

Photodynamic therapy (PDT) is a non-invasive and very powerful method to kill cancer cells by singlet oxygen ($^1O_2$) generated through light and a photosensitizer (PS).[1,2] Several PSs, mainly porphyrin derivatives are approved for the PDT treatment for different types of cancer such as skin, lung, bladder, and breast cancer.[3] In malign breast cancer cells the pH value can be more acidic and the Na^+ level is up to five times higher than in benign cells (raising from around 20 mM to over 100 mM Na^+).[4] A very powerful and non-invasive but costly technique to visualise Na^+ in the human body is based on magnetic resonance imaging (MRI) of ^{23}Na.[5] A more cost-effective method to image Na^+ *in vivo* is the use of fluorescence spectroscopy.[6,7] For precise identification and targeted light irradiation of tumor tissue, a fluorescence imaging-guided PDT is very helpful.[8,9] A further class of promising triplet PSs for PDT are based on boron-dipyrromethene (BODIPY) dyes,[10–12] when for instance substituted in 2,6-position with heavy atoms such as iodine[13–15] or bromine.[16] Two decades ago, the group of Akkaya *et al.* reported on 2,6-dibromo-substituted F-BODIPYs as triplet PSs to efficiently produce $^1O_2$.[16] Further, O'Shea *et al.* published a while ago, that the $^1O_2$ generation rate can be regulated by protons.[17] There, a photoinduced electron transfer (PET) is blocked by protonation of an amine donor.[17] Moreover, in a pioneering work Akkaya *et al.* showed that a PS consisting of 2,6-diiodo- and 3,5-dipyridylethenyl-substituted F-BODIPY equipped in *meso*-position with a benzo-15-crown-5 can modulate and enhance $^1O_2$ production by both H^+ and Na^+ in acetonitrile (ACN).[18] Meanwhile, some factors that control the $^1O_2$ efficiency have been uncovered such as pH, light, hydrogen peroxide, nucleic acids, proteins *etc.*[18–21]

In a recent study, we reported on a benzo-15-crown-5-equipped F-BODIPY dye **1a** (Fig. 1) for a reliable fluorescence detection of Na^+ in the pH range from 3 to 10 by fluorescence enhancement caused by an off-switching of a PET by Na^+ in aqueous solution.[22] Herein, we now report on a detailed experimental and theoretical study of the regulation of $^1O_2$ exclusively by Na^+ and the fluorescence sensing of Na^+ by a PS in ACN and aqueous solution. Our overriding goal is to design a PS which shows an enhanced $^1O_2$ production as well as an enhanced fluorescence response only in malign, but not in benign tissue. As a trigger we selected the enhanced Na^+ level in breast cancer cells. By fine tuning the Na^+ complexing abilities of the Na^+-responsive PS (dissociation constant K_d) we aimed to manipulate the $^1O_2$ evolution and fluorescence response. We designed PS **1** to be both, a therapeutic and an imaging agent regulated by the enhanced Na^+ level in tumor tissue. PS **1** is a combination of the photostable triplet PS **2**,[23] a 2,6-dibromo-substituted F-BODIPY dye, and the pH-stable and Na^+-selective binding unit **3**, benzo-15-crown-5[24] (Fig. 1).

2. Results and discussion

A bromination at positions 2 and 6 of the F-BODIPY **1a**[22] with *N*-bromosuccinimide (NBS) yielded the novel PS **1** in a

moderate yield of 47%.[25] As references, the F-BODIPYs **2** and **2a** without benzo-15-crown-5 moiety were synthesized as described.[22,26] Benzo-15-crown-5 (**3**) is commercially available. The novel PS **1** was characterized by ^1H and ^{13}C NMR spectroscopy as well as electrospray ionization mass spectrometry.[25] The molecular structure of **1** was confirmed by X-ray analysis (Fig. 1).[25] Single crystals of **1** were obtained by slow solvent evaporation (ethyl acetate/hexane, v/v, 1/1). At first, we recorded UV/Vis absorption spectra of **1** and **2** in ACN (Fig. S2a). The absorption spectra of **1** and **2** are very similar, in the range from 350 nm to 550 nm, to each other. They show the most intense absorption band (S_0 to S_1 transition) with a local maximum (λ_{max}) at about 525 nm (vibronic 0–0 state) with a shoulder at about 490 nm (vibronic 0–1 state).[27] The molar extinction coefficients (ε_λ) at λ_{max} for **1** (77 000 M^{-1} cm^{-1}) and **2** (75 000 M^{-1} cm^{-1}) in ACN are comparable to each other, suggesting that the phenylic substituent in *meso*-position of the F-BODIPY in **1** does not significantly extend the π-electron system of the F-BODIPY chromophore. As found in the molecular structure of **1** the phenyl ring is almost orthogonal to the planar F-BODIPY core (dihedral angle 86.1°, Fig. 1) which electronically decouples the F-BODIPY from the benzo-15-crown-5. Then, we recorded UV/Vis absorption spectra of **1** and **2** ($c_{dye} = 10^{-5}$ M and 10^{-6} M, respectively) in different ACN/water mixtures and found a good solubility of **1** and **2** up to a ACN/water mixture of 1/9 (v/v) (Fig. S2c–f), but **2** showed a blue shift of λ_{max} when the water amount was increased (Fig. 2d and f).[25] Thus, **2** is only an appropriate spectroscopic reference compound for **1** in ACN. Moreover, to ensure complete solubility of **1**, we decided for further investigation to use as an aqueous solution an ACN/water mixture of 1/3 (v/v). Further, the fluorescence emission maxima of **1** and **2** ($c = 10^{-6}$ M) were also very similar to each other in ACN (539 nm (**1**) and 540 (**2**)) (Fig. S6a), but their fluorescence quantum yields (Φ_f) differ from each other (Φ_f = 0.010 (**1**), Φ_f = 0.207 (**2**)).[25] The low Φ_f value of **2** is caused by a heavy atom quenching effect which is typical for a triplet PS.[28] Probably, in **1** an additional quenching process, such as in **1a** (Φ_f = 0.258[22] in ACN(**1a**)), a reductive PET from the benzo-15-crown-5 (electron donor) to the excited and decoupled 2,6-dibrominated F-BODIPY core (electron acceptor)

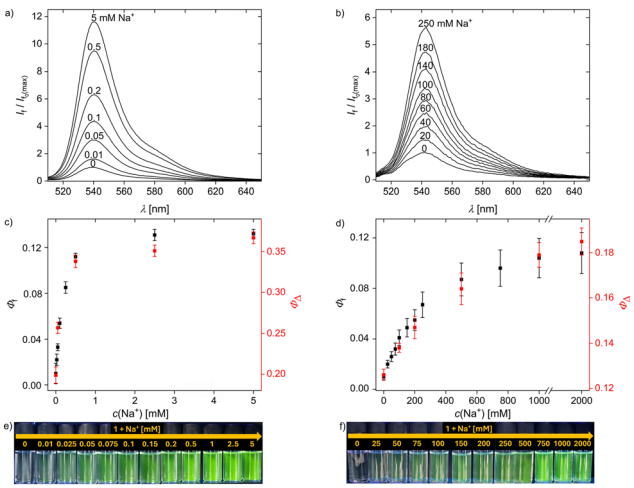

Fig. 2 Fluorescence intensity (I_f) of **1** ($c = 10^{-6}$ M, λ_{ex} = 500 nm) in the presence of different Na^+ concentrations (a) in ACN and (b) in ACN/water, (v/v, 1/3). Fluorescence quantum yields (Φ_f) (black) and singlet oxygen quantum yields (Φ_Δ) (red) of **1** in the presence of different Na^+ concentrations (c) in ACN and (d) in ACN/water (v/v, 1/3). Photographs under UV light (366 nm) of **1** ($c = 10^{-6}$ M) in the presence of different Na^+ concentrations (e) in ACN and (f) in ACN/water (v/v, 1/3).

occurs.[29–31] Solvent effects on the Φ_f values for **1** are found because the reductive PET in **1** is more favorable in polar solvents (Table S3).[25] The low Φ_f values of **1**, **1a** and **2** in polar solvents make them suitable candidates as PS to produce efficiently $^1O_2$ in ACN and aqueous solution. Then we monitored the $^1O_2$ production by recording the absorbance of 1, 3-diphenylisobenzofuran (DPBF) as a singlet oxygen scavenger at 410 nm in ACN, aqueous solution (ACN/water, v/v, 1/3) and 1,4-dioxane/dimethyl sulfoxide (v/v, 99/1).[25] The following singlet oxygen quantum yields (Φ_Δ) were calculated: 0.199 ± 0.010 for **1**, 0.239 ± 0.010 for **1a** and 0.495 ± 0.092 for **2** in ACN, 0.527 ± 0.012 for **1**, 0.048 ± 0.002 for **1a** and 0.521 ± 0.014 for **2** in 1,4-dioxane/dimethyl sulfoxide (v/v, 99/1) as well as for **1** 0.126 ± 0.003 in aqueous solution (ACN/water, v/v, 1/3). The triplet PS **2** generates more $^1O_2$ than **1** and **1a** in ACN and exhibits very similar Φ_Δ values in both polar and non-polar

solvents. The intersystem crossing (ISC) process in **2**, caused by the heavy atom effect of the two bromine atoms, results in a well populated triplet state (T_1), which is less dependent on the solvent polarity.[25,32] The PS **1** exhibits a similar Φ_Δ value in non-polar environments to that of **2**, and shows a higher Φ_Δ value compared to its behaviour in more polar solvents. In contrast, **1a** displays the opposite trend: it has a higher Φ_Δ value in polar solvents and a lower Φ_Δ value in non-polar environments. In **1**, two deactivation pathways from the S_1 state to the T_1 state are conceivable. Firstly, ISC, which is typical for heavy atom containing triplet PS,[13,16,28] and secondly, a spin–orbit charge-transfer (SOCT)-ISC process, which predominates in heavy atom-free triplet PS,[33–36] such as PET-based PS, where a charge-separated ^{1}CT state is formed and stabilized in polar solvents.[34] In general, the SOCT-ISC proceeds much faster than the ordinary ISC between π to π* states.[37] For the heavy atom-free triplet PS **1a**, we observed a higher Φ_Δ value in polar solvents compared to the reference F-BODIPY **2a** (Φ_Δ = 0.09 in ACN).[38] This enhancement is likely due to a SOCT-ISC process facilitated by the polar environment. Moreover, we observed similar Φ_Δ values for **1** and **1a** in ACN, indicating that in both PS, the SOCT-ISC is likely the predominant pathway from the ^{1}CT state to the T_1 state, in **1** the SOCT-ISC process likely predominates in polar solvents whereas conventional ISC is more dominant in non-polar environments.[25]

Further, we recorded UV/Vis absorption spectra of **1** ($c = 10^{-5}$ M) in the presence of Na^+ in ACN and in an ACN/water mixture of 1/3 (v/v) (Fig. S3a and b). The absorption at 540 nm (λ_{max}) is nearly unaffected by Na^+. The complexation of Na^+ within the benzo-15-crown-5 in **1** can be observed by an enhanced blue-shift of the π → π* transition from around 280 nm to 270 nm, (Fig. S3a and b) which is typical for cation complexation of benzo-crown ethers.[39] Then, we measured the influence of Na^+ on the fluorescence intensity (I_f), Φ_f and Φ_Δ of **1** in ACN and aqueous solution (ACN/water, v/v, 1/3). The I_f of **1** is enhanced with increasing Na^+ concentrations in ACN and aqueous solution (ACN/water, v/v, 1/3) (Fig. 2a and b). The relative course of both titration curves (λ_{em} = 540 nm, Fig. S7b and d) is similar but the maximum FE is reached at different Na^+ concentrations, in ACN at 5 mM and in aqueous solution (ACN/water, v/v, 1/3) at 2 M, respectively. The fluorescence enhancement factor (FEF) induced by Na^+ in ACN is 11.6 ± 0.1 at 5 mM Na^+ and in ACN/water (v/v, 1/3) is 9.1 ± 0.5 at 2 M Na^+, respectively. We also observed an enhancement of the Φ_f values of **1** in the presence of different Na^+ concentrations in ACN and aqueous solutions (ACN/water, v/v, 1/3) (Fig. 2c, d and Tables S4, S5). Here, we observed the highest Φ_f value for **1** at 5 mM Na^+ in ACN (Φ_f = 0.132 ± 0.004) and in aqueous solution (ACN/water, v/v, 1/3) at 2000 mM Na^+ (Φ_f = 0.108 ± 0.016). Probably, the FE is caused by blocking the PET process in **1** by Na^+, as also found for **1a** + Na^+.[22] Na^+ raises the oxidation potential of the PET electron donor benzo-15-crown-5 in ACN and aqueous solution.[40] Therefore, the reductive PET process in **1** + Na^+ becomes more unlikely as expressed by the Rehm–Weller equation.[30] Moreover, we also determined an enhanced Φ_Δ value for **1** in the presence of different Na^+ concentrations in both ACN and aqueous solution (ACN/water, v/v, 1/3), (Fig. 2c, d and Tables S1, S2). We also observed the highest Φ_Δ value for **1** at 5 mM Na^+ in ACN (Φ_Δ = 0.367 ± 0.007) and in aqueous solution (ACN/water, v/v, 1/3) at 2000 mM Na^+ (Φ_Δ = 0.185 ± 0.006). Moreover, we determined for **1a** + 5 mM Na^+ a Φ_Δ value of 0.137 ± 0.006 in ACN which is close to the Φ_Δ value of 0.09 of **2a** in ACN.[38] Overall, we observed for **1** an enhancement of I_f, Φ_f and Φ_Δ by Na^+ and for **1a** an enhancement of I_f and Φ_f but a reduction of Φ_Δ by Na^+ in polar solvents. Further, we calculated the limit of detection (LOD) from the fluorescence titration data of **1** + Na^+ (LOD = $3\sigma/m$) in ACN and aqueous solution (ACN/water, v/v, 1/3).[25] The PS **1** shows a lower sensitivity towards Na^+ in ACN with a LOD of (9.45 ± 0.6) μM as in aqueous solution (ACN/water, v/v, 1/3) (11.5 ± 1.1) mM, respectively (Fig. S9a and b). We also found a good linear relationship between the fluorescence intensity of **1** + Na^+ in ACN and aqueous solution (ACN/water, v/v, 1/3) (from 0 mM to 0.14 mM Na^+, R^2 = 0.9966 (ACN), from 0 mM to 100 mM Na^+, R^2 = 0.9992 (ACN/water, v/v, 1/3), Fig. S9a and b) at 540 nm, respectively. More importantly, we calculated from the fluorescence intensity changes of **1** + Na^+ their dissociation constants (K_d) in ACN and in aqueous solution (ACN/water, v/v, 1/3) resulting in K_d values of (0.16 ± 0.02) mM and (209 ± 5) mM, respectively.[25] The latter K_d value of **1** + Na^+ in aqueous solution is biologically relevant, since it is close to the Na^+ level in malign breast cancer cells.[4] The K_d value of **1** + Na^+ is significantly lower in ACN than in aqueous solution caused by the fact that a solvent like ACN that does not coordinate strongly with Na^+ and a complexation of Na^+ within the benzo-15-crown-5 is less hampered. In addition to it, the slopes of the plots for **1** + Na^+ ($\log(c_{Na^+})$ *vs.* $\log[(I_f - I_{f\,min})/(I_{f\,max} - I_f)]$) in ACN and aqueous solution (ACN/water, v/v, 1/3) were nearly 1 (Fig. S8a and b),[25] suggesting a 1 : 1 binding ratio between Na^+ and **1**. Moreover, to elucidate the binding stoichiometry between **1** with $NaClO_4$ in solution, we carried out ^{1}H NMR experiments in CD_3CN (Fig. S12).[25] Thus, a 1 : 1 binding stoichiometry of **1** with $NaClO_4$ was confirmed by a Job's plot analysis (Fig. S13).[25] We observed a downfield shift of the benzo-15-crown-5 protons until one equivalent $NaClO_4$ in the ^{1}H NMR spectra of **1** (Fig. S12) assuming that Na^+ is coordinated within the benzo-15-crown-5 in **1**.

EPR experiments were carried out with 2,2,6,6-tetramethyl piperidine (TEMP) as a $^1O_2$ specific spin-trap agent.[25] It was added to **1** and **1** + 5 mM $NaClO_4$, and a strong EPR signal of 2,2,6,6-tetramethylpiperidinyloxyl (TEMPO) was observed after light irradiation in ACN (Fig. S30). We found for **1** + 5 mM $NaClO_4$ a two times higher intensity of the TEMPO signal at 336.58 mT than for **1** indicating that in the presence of Na^+ more $^1O_2$ is produced.

We further investigated the influence of varying aqueous pH values on the fluorescence performance of **1**.[25] **1** shows very stable invariant fluorescence emission signals in the pH value range from 3.04 to 10.04 (Fig. S11a). Moreover, we observed for **1** in ACN and aqueous solution (ACN/water, v/v, 1/3) over a time period of 360 min a relatively photostable fluorescence signal at 540 nm (Fig. S11b) meaning that the photobleaching of **1** is negligible. To verify selectivity of **1** for Na^+ towards other important biological cations such as Li^+, K^+, NH_4^+, Mg^{2+}, Ca^{2+}, Mn^{2+}, Fe^{3+}, Cu^{2+} and Zn^{2+}, we measured the fluorescence

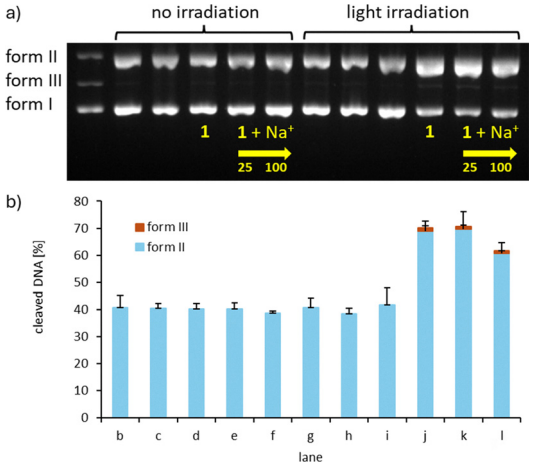

Fig. 3 (a) Nuclease activity towards plasmid DNA pBR322 (0.025 μg μL^{-1}) of PS **1** (c = 200 μM) in Tris buffer (5 mM, pH 7.4) w/wo NaCl (25 or 100 mM). Samples in lanes g–l were incubated under irradiation by green light for 50 min whereas samples in lanes a-f were not irradiated. Lane a: DNA ladder (form I, II and III), lane b + g: DNA reference, lanes c + i: 100 mM NaCl, lanes d + j: **1**, lanes e + k: **1** + 25 mM NaCl, lanes f + l: **1** + 100 mM NaCl, lane h: 25 mM NaCl. (b) Visualization of the extent of DNA cleavage in percent with standard deviation as error bars.

intensities in the presence of these cations at their respective concentrations that are biologically relevant in aqueous solution (ACN/water, v/v, 1/3).[25] The fluorescence performance of **1** is only slightly impacted (Fig. S10), showing that **1** is a Na^+-selective fluorescent imaging tool.

Moreover, we tested the DNA cleavage activity of **1** (c = 200 μM) with plasmid DNA at pH 7.4 with or without green light irradiation in the absence or presence of NaCl (Fig. 3) or $NaClO_4$ (Fig. S28). Degradation of supercoiled DNA (form I) to open-circular/nicked (form II) and linear DNA (form III) was monitored *via* gel electrophoresis.[25] Under green light irradiation, we observed DNA cleavage by **1** (lane j) forming 69% DNA form II (single-strand breaks) and even 1% form III (double-strand breaks). When the sample was not irradiated, no cleavage activity of **1** was observed (lane d about 40% form II). Surprisingly, the cleavage activity is not enhanced by NaCl (lanes k and l, Fig. 3) or $NaClO_4$ (Fig. S28). Probably, the stabilisation of the negatively charged DNA double helix (phosphate backbone) by Na^+ due to electrostatic interactions[41] results in a lower DNA cleavage activity of **1**.

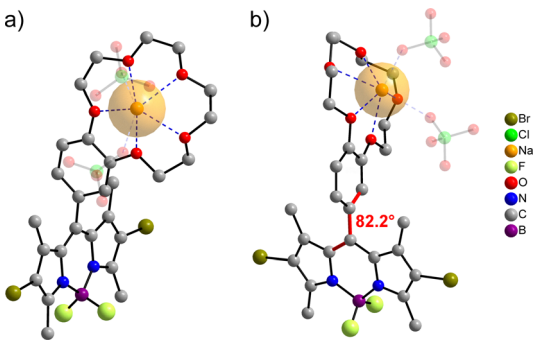

Fig. 4 Molecular structure of [Na(**1**)ClO_4] with a space-filling model of Na (crystal radius[42] regarding coordination number). (a) Front view and (b) side view. H atoms are omitted for clarity.

Further, we crystallized **1** with $NaClO_4$ in a molar ratio of 1 : 1 from a chloroform/acetonitrile (v/v, 3/1) mixture to get more insights on the binding characteristics of Na^+ within **1**. X-ray analysis provided the molecular structure of the Na^+ complex [Na(**1**)(ClO_4)] (Fig. 4). Na^+ is mainly coordinated by the five oxygen atoms of the benzo-15-crown-5 in **1** and shows a good fit-in-size into the cavity (Fig. 4a). Notably, the two symmetry-equivalent bridging perchlorate anions are disordered which influences the total number of coordination bonds of the Na^+ (Fig. S23 and S24). We also found an electronic decoupling of the F-BODIPY from the Na^+ complexed benzo-15-crown-5 unit because in the molecular structure of [Na(**1**)(ClO_4)] the phenyl ring is almost orthogonal to the planar F-BODIPY core (dihedral angle 82.2°, Fig. 4b).

Complementary to the experiments, we performed (time-dependent) density functional theory [(TD-)DFT] and singlet/triplet spin–orbit coupling (SOC) calculations of **1**, a dibromine-free F-BODIPY dye **1a** and **2** at the B3LYP/def2-TZVP level of theory[43–45] in ORCA 6.0.[25,46] The bright S_1 state of **1** in Fig. 5c is given by a local transition on the BODIPY part from MO_{Dye} to the LUMO, while the optically dark ^{1}CT state shows strong charge transfer character from MO_{CT} to the LUMO. We find that the addition of Na^+ leads to an energetic stabilization of the MO_{CT}, while the two BODIPY-localized MOs remain mostly unaffected as shown in Fig. 5d due to the greater spatial distance to the crown ether part of **1**. The excitation energy of the ^{1}CT state is thus increased relative to the bright S_1 state after Na^+ complexation in agreement with the reported experimental findings.[25] Furthermore, bromination leads to a one order of magnitude increase in the computed singlet/triplet SOCs of **1** compared to **1a** due to the heavy-atom effect of the bromine atoms.[25]

Overall, the fluorescence quenching observed for **1** is likely due to a reductive PET process. In polar solvents, a ^{1}CT state is formed and stabilized, and its conversion to T_1 state *via* a SOCT-ISC mechanism is probable. The resulting T_1 state subsequently generates a moderate amount of $^1O_2$ in polar solvents. Furthermore, we assume that Na^+ interrupts the reductive PET process in **1** in polar solvents, leading to an increase in the energy of the ^{1}CT state. As a result, population of the T_1 state *via* ISC, facilitated by the heavy atoms (bromine), becomes more favourable and efficient, thereby restoring both fluorescence and $^1O_2$ generation of the dibrominated F-BODIPY core (Φ_f and Φ_Δ values of **2** in polar media). As a result we observed for **1** + Na^+ higher Φ_f and Φ_Δ values compared to **1** without Na^+ (Fig. 5a and b). The latter can lead to degradation of DNA under irradiation (Fig. 3a and b). Moreover, we found for the dibromine-free F-BODIPY dye **1a** in the presence of Na^+ also an enhanced Φ_f value but a reduced Φ_Δ value in polar solvents. The presence of Na^+ blocks the reductive PET process in **1a**, resulting in an elevation of the ^{1}CT energy level. This effectively restores the fluorescence of the dibromine-free F-BODIPY core, where intersystem crossing (ISC) is considered highly unlikely (Fig. S34a and b). To the best of our knowledge, this is the first report that only a metal ion, here Na^+, regulates $^1O_2$ evolution. The enhanced $^1O_2$ production by Na^+ can be useful to selectively kill malign cancer cells after

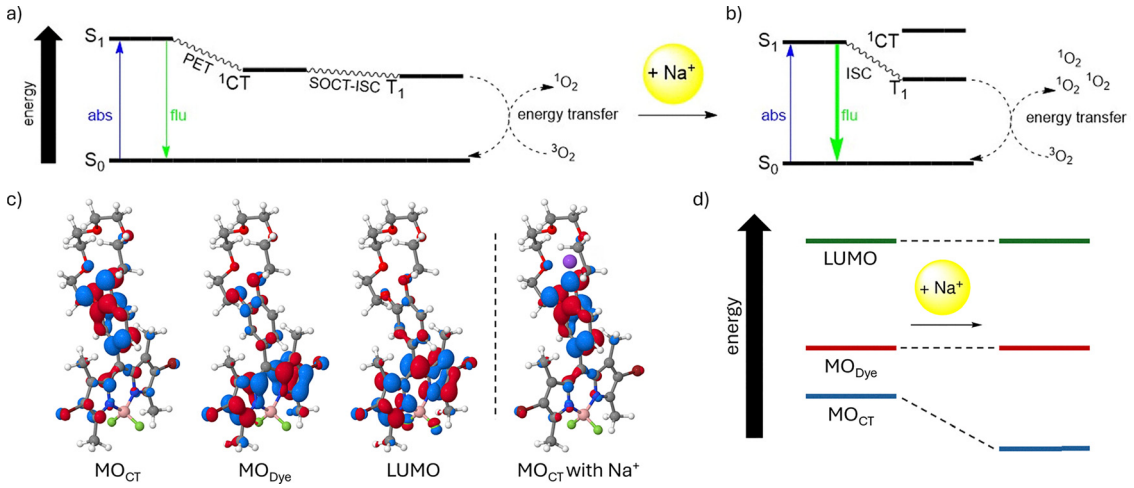

Fig. 5 Jablonski diagram of the postulated mechanism of the photosensitized production of $^1O_2$ in the PS **1** in polar solvents (a) without Na^+ and (b) with Na^+. irradiation when the K_d value of the Na^+-selective PS fits to the Na^+ levels in the cancer cells.

3. Conclusions

In summary, we synthesized the novel and Na^+ selective PS **1** consisting of a benzo-15-crown-5 and a dibrominated F-BODIPY dye shows a fluorescence signal which is photostable and invariant to a wide pH value range from 3.04 to 10.04. Further, **1** is a fluorescent tool with high Na^+ selectivity and Na^+ sensitivity, fast Na^+ response and the Na^+ induced fluorescence enhancement is even recognizable with the naked eye after irradiation with UV light. Moreover, we observed higher Φ_f and Φ_Δ values for **1** in the presence of Na^+ in polar solvents. The K_d value of **1** + Na^+ is (209 ± 5) mM in aqueous solution and fits better to the Na^+ level in malign cancer cells (around 100 mM Na^+) than to benign cells (around 20 mM Na^+).[4] PS **1** is a suitable therapeutic as well as a Na^+ imaging agent. **1** could be a useful PS for cancer therapy because **1** could image tumorous tissue, and targeted light irradiation would selectively kill cancer cells through $^1O_2$ generation. Currently, we are designing PSs applicable in PDT for a deeper tissue penetration by extending the π-system in position 2 and 5 of the F-BODIPY core to shift absorbance to the near-infrared (NIR) region.[47]

29 For **1**, a reductive PET process from the benzo-15-crown-5 to the dibrominated F-BODIPY core has a negative ΔG_{PET} value of −0.03 eV according to the Rehm-Weller equation $\Delta G_{PET} = E_{ox} - E_{red} - \Delta E_{00} - \Delta G_{ion\text{-}pair}$.[27] The oxidation potential (E_{ox}) of benzo-15-crown-5 is 1.00 V and the reduction potential (E_{red}) of **2** is −1.20 V *vs.* $Ag/AgNO_3$ as the reference electrode in ACN.[23] In ACN, the ΔE_{00} value of 2 (533 nm) is about 2.33 eV (transition energy between the vibrationally relaxed ground and excited state of the fluorophore).[23] The attractive energy, $\Delta G_{ion\text{-}pair}$ is assumed to be −0.1 V.[28].
