# Photocatalytic NO<sub>x</sub> removal and recovery: progress, challenges and future perspectives

Ting Xue,<sup>a</sup> Jing Li,<sup>a</sup> Lvcun Chen,<sup>b</sup> Kanglu Li,<sup>b</sup> Ying Hua,<sup>a</sup> Yan Yang<sup>id</sup> \*<sup>cd</sup>  
and Fan Dong<sup>id</sup> \*<sup>a</sup>

The excessive production of nitrogen oxides (NO<sub>x</sub>) from energy production, agricultural activities, transportation, and other human activities remains a pressing issue in atmospheric environment management. NO<sub>x</sub> serves both as a significant pollutant and a potential feedstock for energy carriers. Photocatalytic technology for NO<sub>x</sub> removal and recovery has received widespread attention and has experienced rapid development in recent years owing to its environmental friendliness, mild reaction conditions, and high efficiency. This review systematically summarizes the recent advances in photocatalytic removal, encompassing NO<sub>x</sub> oxidation removal (including single and synergistic removal and NO<sub>3</sub><sup>-</sup> decomposition), NO<sub>x</sub> reduction to N<sub>2</sub>, and the emergent NO<sub>x</sub> upcycling into green ammonia. Special focus is given to the molecular understanding of the interfacial nitrogen-associated reaction mechanisms and their regulation pathways. Finally, the status and the challenges of photocatalytic NO<sub>x</sub> removal and recovery are critically discussed and future outlooks are proposed for their potential practical application.

## 1 Introduction

Nitrogen oxides (NO<sub>x</sub>, consisting of 95% NO and NO<sub>2</sub>) are pervasive air pollutants which are implicated in various environmental events (acid rain, photochemical smog, and global warming) and cause detrimental impacts on public health.<sup>1–3</sup> They serve as key precursors for the formation of emerging tropospheric ozone, PM<sub>2.5</sub> as well as secondary organic aerosol pollution.<sup>2,4</sup> Although there are NO<sub>x</sub> from natural sources, anthropogenic activities, particularly fossil fuel combustion, account for a major contribution to the global NO<sub>x</sub> emissions in the atmosphere.<sup>5,6</sup>

While NO<sub>x</sub> is a pollutant, it can also be recognized as an energy feedstock. With a high reactivity, NO<sub>x</sub> possesses the potential to be utilized for the synthesis of valuable N-containing chemicals. Ammonia (NH<sub>3</sub>) is indeed an indispensable chemical for fertilizers,<sup>7</sup> dyes,<sup>8</sup> polymers,<sup>9</sup> explosives,<sup>10</sup> resins,<sup>10</sup> *etc.*, and can serve as a carbon-neutral energy carrier.<sup>11</sup> The industrial production of NH<sub>3</sub> synthesis currently heavily relies on the Haber–Bosch route, which requires harsh conditions (400–500 °C, 150–300 atm), resulting in more than 2% of

global energy consumption.<sup>12,13</sup> This high energy consumption is also largely derived from fossil fuels.<sup>14</sup> Faced with global energy shortages, recovery of NO<sub>x</sub> to NH<sub>3</sub> gives an alternative route for both environmental control and nitrogen resource utilization.

Photocatalytic technology powered by renewable solar energy has been reckoned as one of the most viable strategies that could convert NO<sub>x</sub> into less harmful or useful products under mild conditions.<sup>15–17</sup> At present, conventional photocatalytic technologies, including NO<sub>x</sub> oxidation, NO<sub>x</sub> decomposition, and selective NO<sub>x</sub> reduction, have been vigorously developed, spanning from material design to elucidation of the underlying mechanisms.<sup>6,18–20</sup> Meanwhile, the tendency of photocatalytic removal of NO<sub>x</sub> has been gradually transformed from oxidation, purification, and then to resource utilization. Particularly, the photocatalytic NO<sub>x</sub> reduction for ammonia synthesis has achieved milestone progress in recent years.

The review aims to summarize recent advancements in photocatalytic NO<sub>x</sub> removal and recovery. The cutting-edge developments in photocatalytic removal in terms of NO<sub>x</sub> oxidation, NO<sub>x</sub> reduction to nitrogen, and NO<sub>x</sub> upcycling to ammonia are comprehensively reviewed. We also highlighted the one-step (NO → NH<sub>3</sub>) and two-step (NO → NO<sub>3</sub><sup>-</sup> → NH<sub>3</sub>) methods as new ideas for simultaneous NO<sub>x</sub> removal and resource utilization. Finally, we discuss the current challenges and provide some perspectives on future directions for NO<sub>x</sub> removal and recovery. The illustration of this review on NO<sub>x</sub> removal and recovery is shown in Scheme 1. We hope that this

review will inspire significant research and essential advancements in the field of photocatalytic  $\text{NO}_x$  removal.

## 2 $\text{NO}_x$ oxidation

### 2.1 Single $\text{NO}_x$ oxidation

**2.1.1  $\text{NO}_x$  oxidation mechanisms.** Photocatalytic oxidation removal is mainly applied to low-concentration pollutant purification. During the photocatalytic reaction process, electron-hole pairs are generated in the catalyst under light irradiation, initiating the oxidation reactions. These pairs migrate to the surface of the photocatalysts and react with adsorbed  $\text{H}_2\text{O}$  and  $\text{O}_2$  molecules, leading to the generation of reactive oxygen species (ROS) such as  $\cdot\text{OH}$ ,  $\cdot\text{O}_2^-$ , and  $^1\text{O}_2$ . These ROS then participate in a series of oxidation reactions with  $\text{NO}$ , ultimately forming the final product  $\text{NO}_3^-$ . Detailed reaction pathways and intermediates involved in this photocatalytic  $\text{NO}$  oxidation process can be described using specific equations, which are supported by relevant ref. 21 and 22:

**2.1.2 Materials for  $\text{NO}_x$  oxidation.** There are three main factors affecting the catalytic performance of photocatalytic oxidation: light absorption, charge carrier separation and transfer, and active site construction.<sup>23</sup> Based on these factors, various modification methods were conducted on  $\text{TiO}_2$ -based materials,<sup>24-27</sup> Bi-based materials,<sup>28-30</sup> g- $\text{C}_3\text{N}_4$ -based materials,<sup>31,32</sup> and perovskite-type materials.<sup>33</sup> Modification methods include but are not limited to metal/non-metal doping, defects, heterojunctions, and sensitization.<sup>34</sup>

Single-atom catalysts have attracted much attention in the field of materials due to their unique activity and effective utilization of active atoms. Several studies have confirmed that single atoms can improve the performance of photocatalysts for

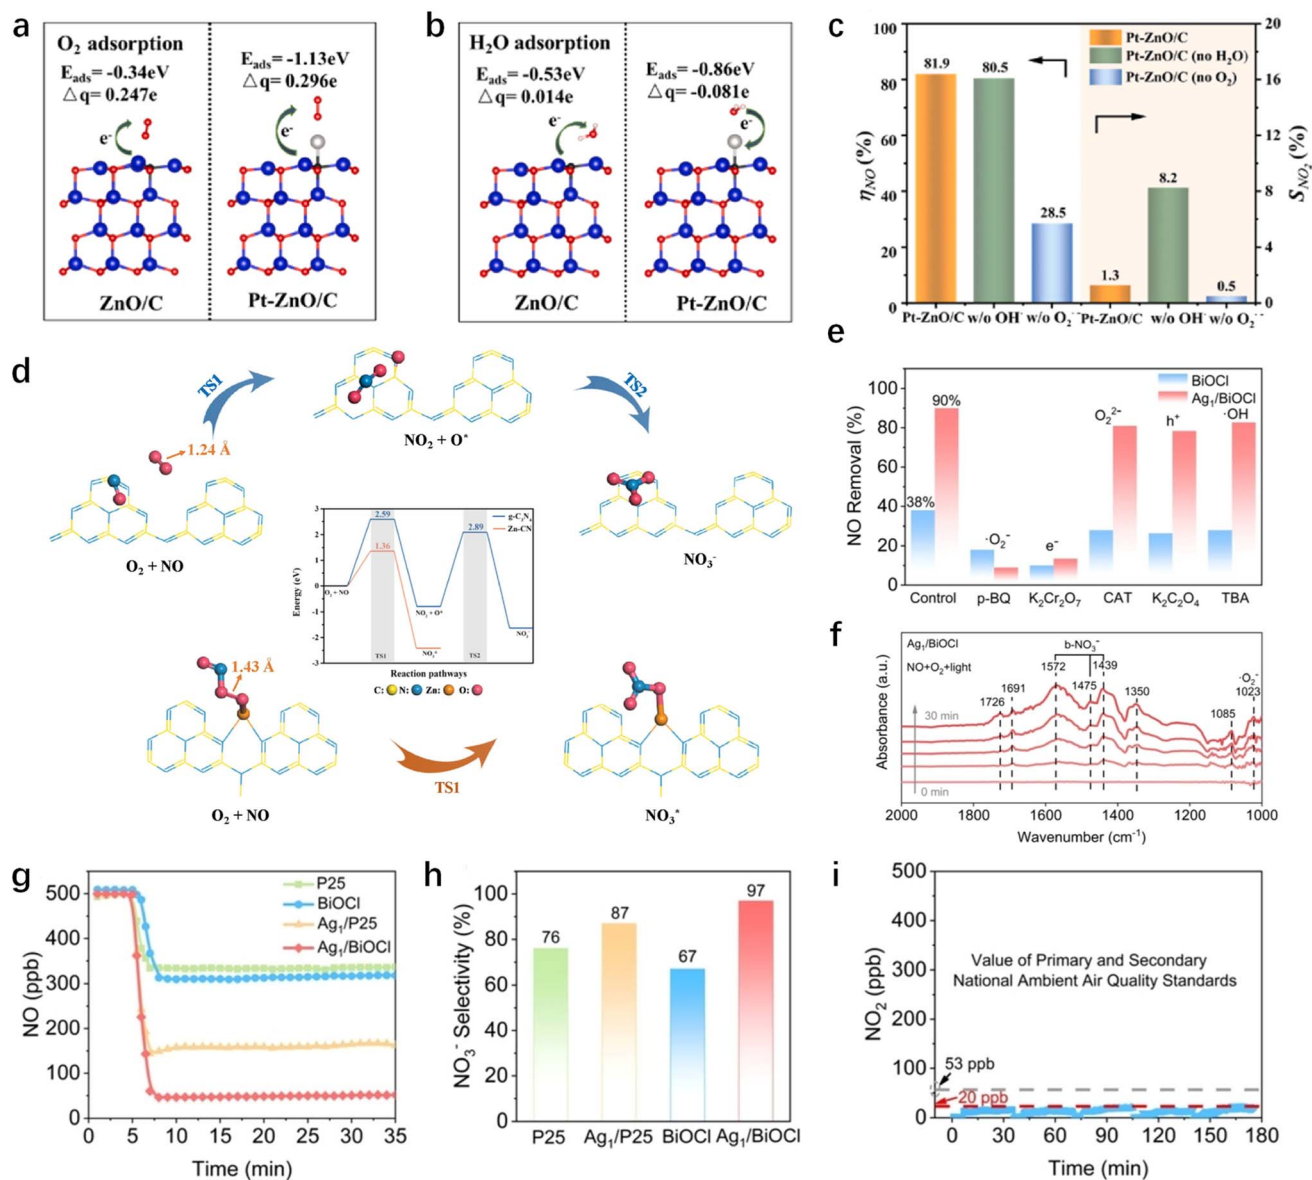

Fig. 1 DFT calculation of (a) O<sub>2</sub> adsorption and (b) H<sub>2</sub>O adsorption on ZnO/C and Pt-ZnO/C surfaces. (c) The NO conversion rate and selectivity of NO<sub>2</sub> formation over the Pt-ZnO/C catalyst in the presence and absence of moisture and O<sub>2</sub>.<sup>36</sup> (d) The NO oxidation process over g-C<sub>3</sub>N<sub>4</sub> and Zn-CN.<sup>37</sup> (e) Photocatalytic NO removal over Ag<sub>1</sub>/BiOCl using different scavengers. (f) DRIFTS spectra of Ag<sub>1</sub>/BiOCl for NO oxidation. (g) NO oxidation of P25, BiOCl, Ag<sub>1</sub>/P25 and Ag<sub>1</sub>/BiOCl. (h) NO<sub>3</sub><sup>-</sup> selectivity of Ag<sub>1</sub>/P25 and Ag<sub>1</sub>/BiOCl under visible light irradiation. (i) The amount of NO<sub>2</sub> generation.<sup>39</sup>

NO<sub>x</sub> removal and provide a convenient way to regulate the generation of ROS for effective pollutant elimination. Liu *et al.*<sup>35</sup> achieved the stabilization of Pt on carbon-defective g-C<sub>3</sub>N<sub>4</sub> by leveraging its affinity with nitrogen atoms resulting from carbon vacancies. The resulting Pd-C<sub>v</sub>-CN catalyst enhances charge transfer efficiency, generating sufficient photoelectrons for the formation of <sup>•</sup>OH and <sup>•</sup>O<sub>2</sub><sup>-</sup> species. This, in turn, facilitates the removal of NO and enhances the selectivity towards NO<sub>3</sub><sup>-</sup>. Hu *et al.*<sup>36</sup> discovered that single Pt atom bridged within a metal-organic framework (MOF)-derived ZnO/C *via* carbon atoms (Pt-ZnO/C) exhibits enhanced adsorption energy and charge transfer characteristics for O<sub>2</sub> and H<sub>2</sub>O (Fig. 1a and b). In

contrast to <sup>•</sup>OH, <sup>•</sup>O<sub>2</sub><sup>-</sup> plays a pivotal role in the conversion of NO<sub>x</sub> to NO<sub>3</sub><sup>-</sup> on a single atom site at the catalytic surface (Fig. 1c). Zhang *et al.*<sup>37</sup> incorporated Zn atoms into the interlayer of g-C<sub>3</sub>N<sub>4</sub>, forming the ZnN<sub>3</sub> structure by linking zinc with three nitrogen atoms. The presence of a single zinc atom facilitated the formation of a Zn-O<sub>2</sub>-NO structure upon adsorption of O<sub>2</sub> and NO, thereby promoting the dissociation of O<sub>2</sub> and the direct conversion of NO to nitrate (Fig. 1d). Simultaneously, the formation of the toxic byproduct NO<sub>2</sub> was inhibited. A similar result enhancement was observed upon doping TiO<sub>2</sub> hollow microspheres (TiO<sub>2</sub>-HMSs) with single atomic Fe.<sup>38</sup> Particularly noteworthy is the effect of silver atoms loaded onto BiOCl (001)

facet-exposed nanosheets, which constructed triangular Cl-Ag<sub>1</sub>-Cl sites on Cl-terminated BiOCl. These sites selectively activated molecular oxygen to  $\cdot\text{O}_2^-$  and enhanced nitrate adsorption by altering the coordination mode of nitrate on the catalyst, thereby preventing nitrate decomposition (Fig. 1e and f).<sup>39</sup> The NO<sub>x</sub> removal efficiency of Ag<sub>1</sub>/BiOCl reached up to 90%, with 97% selectivity for NO<sub>3</sub><sup>-</sup> and minimal emission of NO<sub>2</sub> (Fig. 1g-i).

In summary, the introduction of single atoms can significantly enhance the adsorption of O<sub>2</sub> and H<sub>2</sub>O molecules and the generation of  $\cdot\text{O}_2^-$  and  $\cdot\text{OH}$ , thereby improving both the performance and nitrate selectivity of the photocatalyst. This provides a facile pathway to manipulate the ROS generation for efficient and selective pollutant removal.

**2.1.3 Machine learning as an analysis tool for NO<sub>x</sub> oxidation.** It is well-known that the performance of NO<sub>x</sub> removal not only depends on catalyst properties but also closely relies on preparation methods and reaction conditions. Although catalyst design and optimization of experimental conditions have been fully explored, the dominant factors affecting the NO<sub>x</sub> removal rate remain unclear. Machine learning (ML) has achieved remarkable progress over the past few decades and has become the most potent tool in the field of data mining and analytics.<sup>40,41</sup> ML methods leverage algorithms to extract insights from vast, intricate, and multidimensional datasets, enabling rapid and precise predictions. Recently, progress has been made in employing ML methods in the photocatalytic NO<sub>x</sub> oxidation process. Li *et al.*<sup>42</sup> achieved success in predicting the NO removal rate in the photocatalytic purification of g-C<sub>3</sub>N<sub>4</sub> catalysts using ML methods like gradient boosting decision trees, eXtreme gradient boosting, and random forests. Their findings indicate that catalyst characteristics, reaction process, and preparation conditions are the primary empirical categories influencing the NO removal rate. They have also unveiled the intricate relationships between the photocatalytic NO removal rate and various influencing factors. This approach, to some extent, mitigates the downsides of traditional experimental work, including high costs, lengthy timelines, and demanding labor.

**2.1.4 NO<sub>3</sub><sup>-</sup> decomposition on the photocatalyst.** The formation of nitrate is a key process of NO<sub>x</sub> oxidation, as nitrate has been considered a permanent sink of NO<sub>x</sub>.<sup>43</sup> However, it undergoes photolysis processes under light irradiation (also called detoxification), especially on the surface of the photocatalyst, which in turn serves as a source of atmospheric nitrogenated compounds.<sup>44-49</sup> TiO<sub>2</sub>, the predominant photocatalyst,<sup>50,51</sup> has been shown to promote nitrate photolysis processes through photochemical interaction.<sup>44</sup> Therefore, exploring the decomposition mechanism of nitrate on the surface of photocatalysts assumes pivotal significance for stabilizing nitrate on the catalyst surface. The enhanced photolysis of nitrate by TiO<sub>2</sub> under UV irradiation can be explained using the following reactions<sup>52-54</sup> (eqn (10)–(19)):

There are two main factors affecting the nitrate decomposition mechanism on the TiO<sub>2</sub>, which are co-adsorbed cations and the coexisting atmosphere. It is suggested that the cations on TiO<sub>2</sub> could inhibit the decomposition of nitrates. The presence of cations enhanced the adsorption of NO<sub>3</sub><sup>-</sup> by forming ion pairs with NO<sub>3</sub><sup>-</sup> and prevented NO<sub>3</sub><sup>-</sup> from binding with light-induced h<sup>+</sup> to generate  $\cdot\text{NO}_3$ .<sup>55,56</sup> The decomposition of nitrates is facilitated by co-existing pollutants in the surrounding environment such as SO<sub>2</sub> and volatile organic compounds (VOCs). SO<sub>2</sub> preferentially reacts with  $\cdot\text{NO}_3$  radicals rather than photoelectrons, resulting in a significant improvement in nitrate decomposition.<sup>57,58</sup> Similar to SO<sub>2</sub>, formaldehyde (HCHO) participated in the transformation of NO<sub>3</sub> to HNO<sub>3</sub> through hydrogen abstraction to promote nitrate decomposition. HCHO converts NO<sub>3</sub><sup>-</sup> on particle surfaces into HNO<sub>3</sub> by reacting with  $\cdot\text{NO}_3$ , and then HNO<sub>3</sub> photolyzes at a faster rate.<sup>55</sup> Interestingly, NO produced from nitrate decomposition may be re-adsorbed on the surface of TiO<sub>2</sub> to promote nitrate decomposition.<sup>59</sup> The N–O bond of NO<sub>3</sub><sup>-</sup> could be activated by NO molecules. Subsequently, photogenerated electrons, captured by NO, facilitate the transformation of NO<sub>3</sub><sup>-</sup> under light irradiation through the NO<sub>3</sub><sup>-</sup> + NO<sup>-</sup> → 2NO<sub>2</sub><sup>-</sup> pathway.<sup>59</sup> It is proposed that addressing the photochemical transformation of surface NO<sub>3</sub><sup>-</sup> may entail suppressing the formation of NO<sup>-</sup> during the photocatalytic NO oxidation process.

Although the well-known photochemical activity of nitrate decomposition is excited around 300 nm,<sup>60</sup> it has been verified that nitrate decomposition could be induced by visible light (λ > 380 nm) on TiO<sub>2</sub>. Wang *et al.*<sup>47</sup> investigated the decomposition of surface NO<sub>3</sub><sup>-</sup> on nmTiO<sub>2</sub> under visible light exposure. By regulating the reaction atmosphere (dry argon, wet argon, and wet air), distinct production of NO and NO<sub>2</sub> is observed (Fig. 2a–c). Through meticulous control of *in situ* DRIFTS experiments, they uncovered different decomposition pathways stemming from different surface coordination modes of the NO<sub>3</sub><sup>-</sup> (Fig. 2d and e). Nitrates generated on photocatalysts exhibit two coordination modes: monodentate nitrate (m-NO<sub>3</sub><sup>-</sup>) and bidentate nitrate (b-NO<sub>3</sub><sup>-</sup>). The m-NO<sub>3</sub><sup>-</sup> decomposition initiated by photo-induced electrons primarily leads to the production of NO and NO<sub>2</sub>. It is indicated that H<sub>2</sub>O and O<sub>2</sub> have a remarkable

Fig. 2 Generation of gas-phase products in (a) dry argon atmosphere, (b) humidity argon atmosphere, and (c) humidity air atmosphere under visible light irradiation. (d) Proposed decomposition mechanism of b-NO<sub>3</sub><sup>-</sup> triggered by visible light photocatalysis: (a) conversion pathway of b-NO<sub>3</sub><sup>-</sup> to m-NO<sub>3</sub><sup>-</sup> under visible light irradiation. (b) Photocatalytic decomposition pathway of produced m-NO<sub>3</sub><sup>-</sup> to NO. (c) Photocatalytic decomposition pathway of produced m-NO<sub>3</sub><sup>-</sup> to NO<sub>2</sub>. (e) Proposed decomposition mechanism of m-NO<sub>3</sub><sup>-</sup>.<sup>47</sup>

influence on the decomposition products of NO<sub>3</sub><sup>-</sup>. The introduction of H<sub>2</sub>O molecules results in dissociation on nmTiO<sub>2</sub>, forming surface hydroxyl groups, which then facilitate the conversion of b-NO<sub>3</sub><sup>-</sup> to m-NO<sub>3</sub><sup>-</sup> through hydrogen bonding interactions.<sup>47</sup> Subsequently, visible-light-driven photocatalytic decomposition led to an enhancement in the concentration of NO<sub>x</sub>. Although O<sub>2</sub> can promote nitrate regeneration through the oxidation process, the effect of H<sub>2</sub>O on NO<sub>3</sub><sup>-</sup> decomposition could not be restrained in the presence of O<sub>2</sub>.

To sum up, the decomposition of nitrate on the surface of active particulate matter TiO<sub>2</sub> under various conditions has been confirmed. Therefore, when exploring the mechanism of oxidative NO<sub>x</sub> removal, it is essential to consider the nitrate decomposition process. This perspective offers valuable insights for a more comprehensive understanding of the photocatalytic reaction.

## 2.2 Synergistic NO<sub>x</sub> oxidation

In the real scenario, NO<sub>x</sub> is typically present alongside other air pollutants. The interaction or combination of NO<sub>x</sub> with other

pollutants, such as volatile organic compounds (VOCs) and sulfur dioxide (SO<sub>2</sub>), can lead to the formation of more severe secondary pollutants, especially under sunlight irradiation.<sup>61–65</sup> In addition to designing effective photocatalysts, it is crucial to address the complexities arising from these multiple pollutants when implementing photocatalytic NO oxidation technology in real reactors at pilot or larger scales.<sup>66</sup>

**2.2.1 Synergistic effect between NO<sub>x</sub> and VOCs.** It has been revealed that there is a certain synergistic effect between NO<sub>x</sub> and VOCs on the specific photocatalysts to inhibit the generation of by-products. Xue *et al.*<sup>67</sup> proposed an enhanced photocatalytic NO removal through the addition of acetaldehyde to Sr<sub>2</sub>Sb<sub>2</sub>O<sub>7</sub> to prevent secondary peroxyacetyl nitrate (PAN) formation. The intermediates NO<sub>2</sub><sup>-</sup> from NO and 'CH<sub>3</sub> from acetaldehyde tend to bond and further oxidize to CH<sub>3</sub>ONO<sub>2</sub>, thus promoting NO removal. Density functional theory (DFT) calculations show that the Gibbs free energy required for the conversion of NO to NO<sub>3</sub><sup>-</sup> in the mixed degradation process is lower compared to that in the individual removal pathways, thereby favoring the deep oxidation to NO<sub>3</sub><sup>-</sup>. Li *et al.*<sup>68</sup>

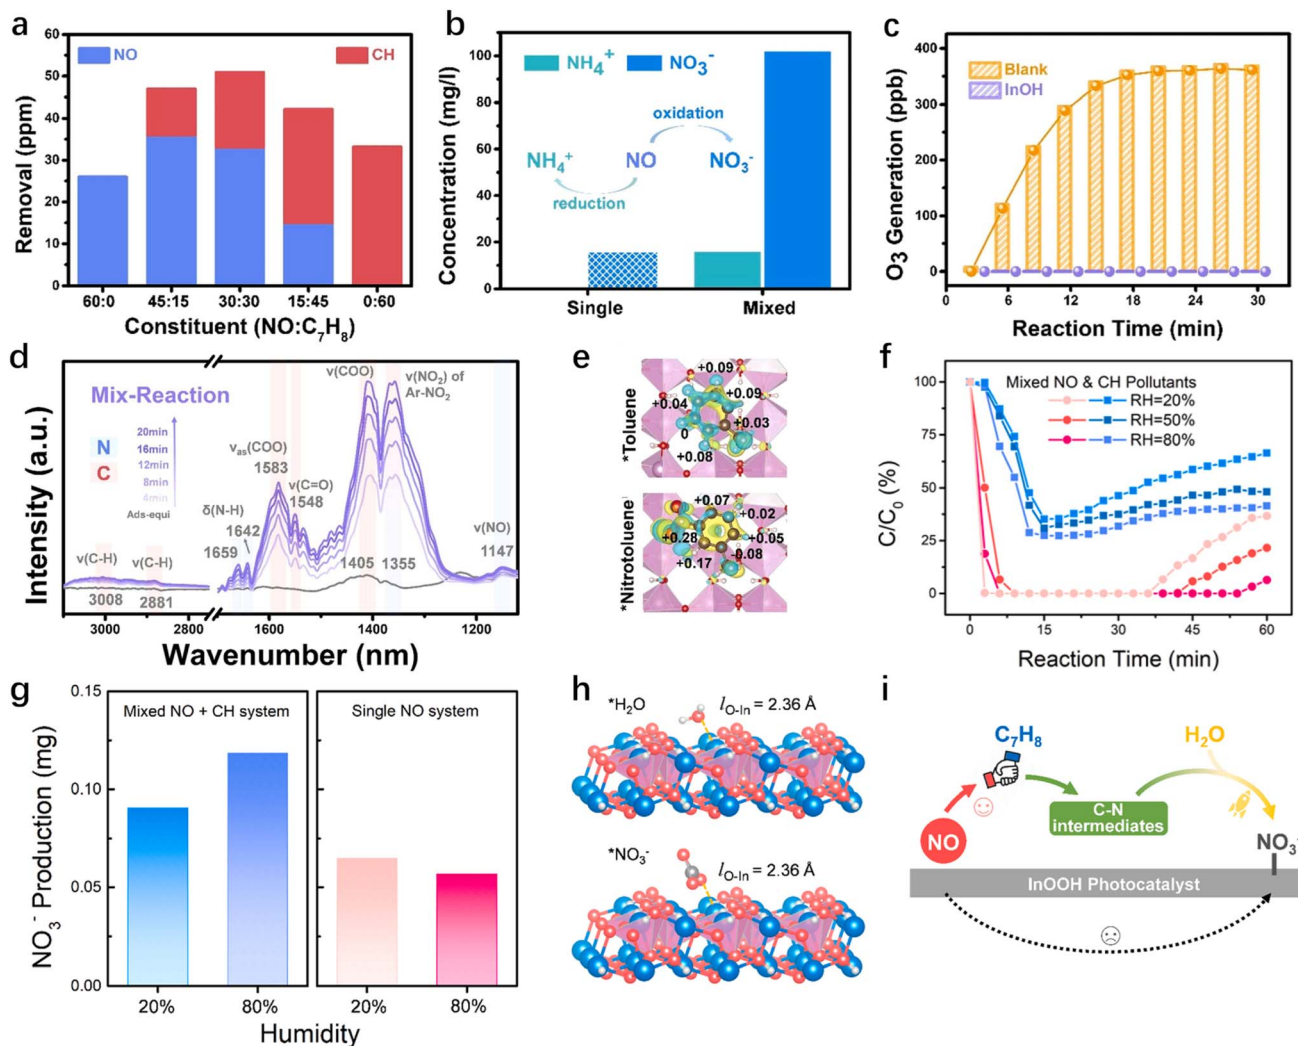

Fig. 3 (a) The removal of NO and C<sub>7</sub>H<sub>8</sub> at different mixing ratios. (b) The nitrogen-containing products identified by IC. (c) The generation of O<sub>3</sub> without and with the photocatalyst under light irradiation. (d) *In situ* DRIFTS spectra for the photocatalytic reaction of NO and C<sub>7</sub>H<sub>8</sub>.<sup>68</sup> (e) Charge distribution of C<sub>7</sub>H<sub>8</sub> and C<sub>7</sub>H<sub>7</sub>NO<sub>2</sub> on the In(OH)<sub>3</sub> photocatalyst; blue and yellow clouds represent charge depletion and accumulation, and the isosurface level is set to 0.0007 eV Å<sup>-3</sup>. (f) Conversion of mixed pollutants at different relative humidities. [NO] = [C<sub>7</sub>H<sub>8</sub>] = 30 ppm. (g) NO<sub>3</sub><sup>-</sup> production in mixed and single systems at different relative humidities. (h) Simulation of reactant and product binding on the catalyst. (i) Illustration of the synergistic interaction between NO and C<sub>7</sub>H<sub>8</sub> and the promoting effect of H<sub>2</sub>O.<sup>69</sup>

investigated the simultaneous degradation of NO and C<sub>7</sub>H<sub>8</sub> (toluene) mixed pollutants. On the In(OH)<sub>3</sub> photocatalyst, NO and toluene exhibit coupling reaction effects and give rise to a new NO conversion pathway, leading to NO deep oxidation to NO<sub>3</sub><sup>-</sup> (Fig. 3a and b). The key intermediate C<sub>7</sub>H<sub>7</sub>NOH is favorable for the NO oxidation to NO<sub>2</sub> to inhibit O<sub>3</sub> formation (Fig. 3c and d). Then NO<sub>2</sub> was inclined to bond with toluene to form C<sub>7</sub>H<sub>6</sub>NO<sub>2</sub>. The incorporation of the nitro group alters the charge distribution within the benzene ring, disrupting the typical distribution of electrons within the π-π stacked structure (Fig. 3e). The rearrangement of electrons opens the benzene ring more readily than toluene, allowing further NO<sub>3</sub><sup>-</sup> formation. This synergistic effect of NO and toluene also occurs in InOOH. The increase in humidity could suppress catalyst deactivation and improve the conversion of mixed pollutants, as shown in Fig. 3f.<sup>69</sup> The yield of nitrate is also consistent with the

conversion efficiency (Fig. 3g). This finding indicates that the extensive occupation of the catalyst surface by nitrate serves as a deactivation factor in mixed pollutant reactions.<sup>69</sup> Under high humidity conditions, H<sub>2</sub>O and NO<sub>3</sub><sup>-</sup> indicate similar adsorption configurations on InOOH, but H<sub>2</sub>O generates more free radicals to directly enhance the conversion of C-N intermediates, thus promoting the conversion of NO to NO<sub>3</sub><sup>-</sup> (Fig. 3h and i).<sup>69</sup> It was also proposed that NO could prevent the deactivation of the photocatalyst due to the incomplete oxidation product NO<sub>2</sub> in the process of o-xylene degradation.<sup>70</sup> NO<sub>2</sub> ensures the generation of a sufficient amount of TiO<sub>2</sub> (•OL) radicals, allowing for the complete mineralization of o-xylene and inhibiting the deactivation of TiO<sub>2</sub>.<sup>70</sup>

**2.2.2 Inhibition effect between NO<sub>x</sub> and SO<sub>2</sub>.** In contrast to VOCs, research indicates that SO<sub>2</sub> tends to hinder the removal of NO<sub>x</sub>. According to the studies of Ao *et al.*,<sup>71</sup> the presence of

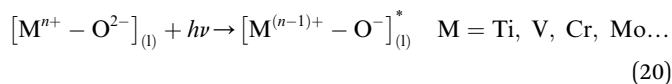

SO<sub>2</sub> resulted in an 8% decrease in NO conversion and a 10% increase in NO<sub>2</sub> generation. The formation of sulfate ions on the catalyst surface obstructed the adsorption sites of TiO<sub>2</sub> for converting NO<sub>2</sub> to HNO<sub>3</sub>, consequently increasing the exit concentration of NO<sub>2</sub>. Chen *et al.*<sup>66</sup> further validated this deactivation mechanism through DFT calculations. The result showed that surface hydroxyls on the (101) facet of TiO<sub>2</sub> create unsaturated coordination of adjacent Ti or O atoms, promoting the adsorption of NO and SO<sub>2</sub>. However, there is a competitive adsorption between NO and SO<sub>2</sub>, as evidenced by the decreasing adsorption energy and charge density. In the oxidation process, SO<sub>2</sub> significantly competes with NO for reaction with <sup>•</sup>O<sub>2</sub><sup>-</sup>. More valence electrons are involved in the oxidation of SO<sub>2</sub>, resulting in higher binding energy between \*O-SOO\* than \*O-NOO\*.

### 3 NO<sub>x</sub> reduction to nitrogen

Contemporary research in photocatalytic NO abatement predominantly centers on oxidizing NO to NO<sub>3</sub><sup>-</sup>. Nevertheless, concerns arise from the production of the more toxic by-product, NO<sub>2</sub>, catalyst deactivation resulting from the obstruction of reaction sites by nitrate products, and the denitrification of NO<sub>3</sub><sup>-</sup>. These challenges impede the practical application of photocatalysts. An alternative approach for NO<sub>x</sub> removal involves the reduction of NO to N<sub>2</sub> without causing deactivation or secondary pollution. This can be achieved through two approaches: direct reduction of NO to N<sub>2</sub> and O<sub>2</sub> under oxygen-free conditions (NO<sub>x</sub> decomposition), and selective reduction of NO to N<sub>2</sub> in a reducing atmosphere (NO<sub>x</sub> photo-selective reduction).

#### 3.1 NO<sub>x</sub> decomposition

The decomposition of NO into harmless N<sub>2</sub> and O<sub>2</sub> represents one of the most desirable pathways of NO removal, as it eliminates the need for additional reductants. Transition metal oxides have emerged as typical photocatalysts for NO<sub>x</sub> decomposition.<sup>72–82</sup> Utilizing zeolite supports allows for the production of highly dispersed powders, enhancing the performance of NO decomposition.<sup>83</sup> Previous studies have demonstrated the significant contribution of transition metal ions to the photocatalytic NO decomposition. As shown in eqn (20), highly dispersed and isolated transition metal oxides form the charge-transfer excited states under irradiation, which involve electron transfer from O<sub>(l)</sub><sup>2-</sup> to M<sub>(l)</sub><sup>n+</sup>:

The selectivity of N<sub>2</sub> increases as the coordination number of the M–O bond decreases, which triggers the photocatalytic decomposition of NO.<sup>83</sup> It was shown that the Ti-oxide/Y-zeolite catalysts with tetrahedral coordination exhibit higher reactivity and selectivity for N<sub>2</sub> generation and lower selectivity for N<sub>2</sub>O formation than those with octahedral coordination.<sup>83</sup> The performance of the photoreduction reaction could also be

improved by oxygen vacancies and doping the catalyst with transition metals.<sup>81,82</sup> van de Krol *et al.*<sup>82</sup> doped TiO<sub>2</sub> nanoparticles with Fe<sup>3+</sup>, which changed the photocatalytic NO removal route from oxidation to reduction (Fig. 4a). The Fe<sup>3+</sup> substituted Ti<sup>4+</sup> in the lattice, and the negative charge of this acceptor-type dopant contributed to the stabilization of positivity-charged oxygen vacancies. The oxygen vacancies could act as active sites to capture the molecular O of the NO molecule and provide light-induced electrons (Fig. 4b). Besides, Ag<sup>0</sup> and Ag<sup>+</sup> coexist on the TiO<sub>2</sub> surface, which both play different roles in the enhancement of N<sub>2</sub> selectivity: the Ag<sup>0</sup> nanoparticles enhance the light absorption of the material, while Ag<sup>+</sup> can decompose the attachment product N<sub>2</sub>O into N<sub>2</sub>.<sup>81</sup> A recent study shows that layered structured perovskite SrBi<sub>2</sub>-Nb<sub>2</sub>O<sub>9</sub> with ultrathin nanostructure and oxygen vacancies (SBNO-UT) is capable of decomposing NO into N<sub>2</sub> and O<sub>2</sub> at the close-to-stoichiometric ratio (Fig. 4c).<sup>84</sup> As can be seen from Fig. 4d, N<sub>2</sub>O intermediates were formed by NO reduction during the photocatalytic process. The *in situ* formed N<sub>2</sub>O bounds to the defective surface, ensuring further reduction (Fig. 4e). Finally, the breakage of the N=O bond completes the reduction of NO to N<sub>2</sub>.

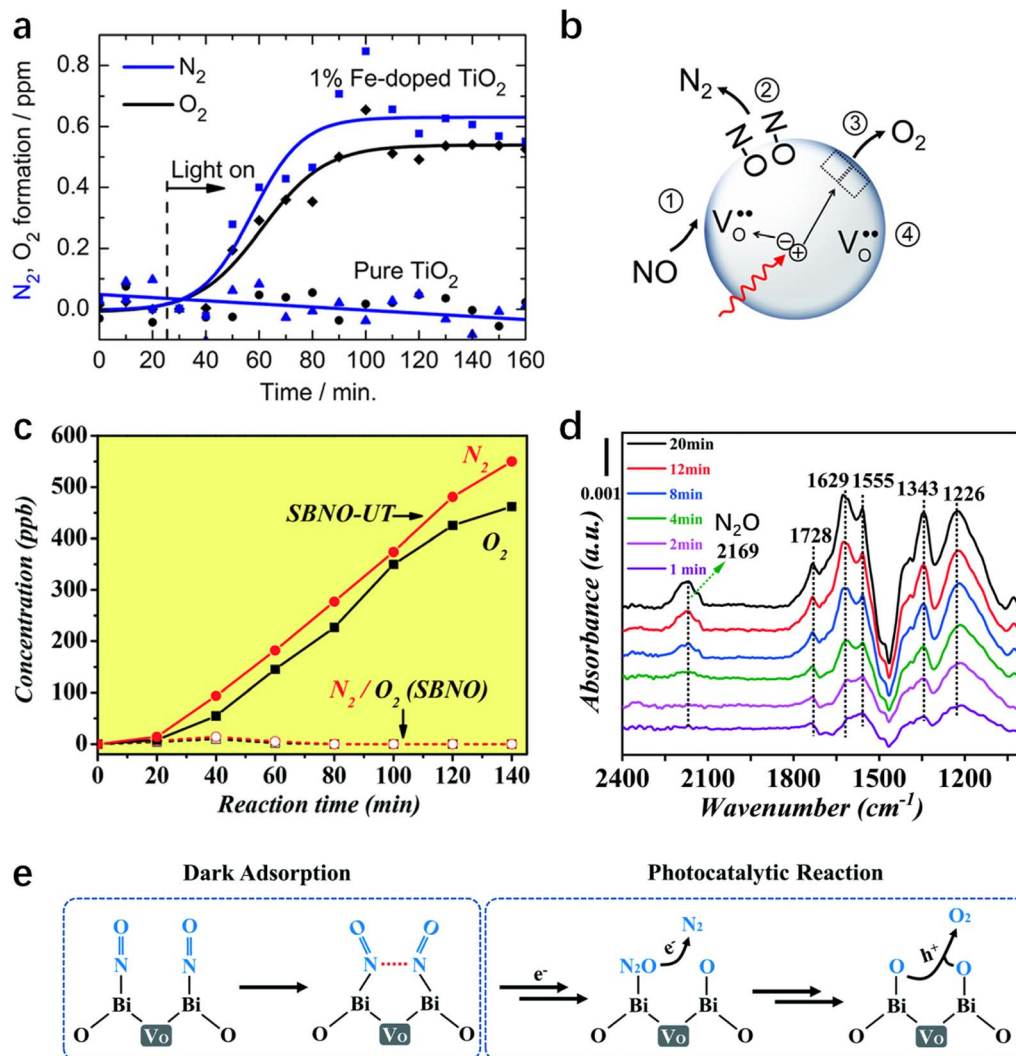

#### 3.2 NO<sub>x</sub> photo-selective reduction

The method of selectively converting NO to N<sub>2</sub> by introducing reducing agents such as NH<sub>3</sub>, CO, H<sub>2</sub>, and hydrocarbons into the system is known as selective catalytic reduction (SCR). Despite extensive study,<sup>85,86</sup> the technology typically operates at high temperatures (300–400 °C),<sup>87,88</sup> leading to relatively high energy consumption and potentially excessive CO<sub>2</sub> emissions. In addressing these challenges, photo-assisted SCR (photo-SCR) of NO<sub>x</sub> with NH<sub>3</sub> using photocatalysts under light irradiation and low-temperature conditions has been developed as an alternative for NO<sub>x</sub> reduction.

NH<sub>3</sub> serves as a common reductant for NO<sub>x</sub> removal by photo-SCR, with TiO<sub>2</sub> being the most extensively utilized catalyst in this system. The reaction mechanism of NO photo-SCR with NH<sub>3</sub> on TiO<sub>2</sub> is depicted in Fig. 5a.<sup>89</sup> There are numerous TiO<sub>2</sub>-based materials for photo-SCR, *e.g.*, TiO<sub>2</sub>/SiO<sub>2</sub>,<sup>90</sup> TiO<sub>2</sub> nanotube arrays,<sup>91</sup> Bi<sub>2</sub>WO<sub>6</sub>/TiO<sub>2</sub> Z-scheme heterojunctions,<sup>92</sup> g-C<sub>3</sub>N<sub>4</sub>/TiO<sub>2</sub> (ref. 93) and Pd-loaded TiO<sub>2</sub>,<sup>94</sup> and Si/TiO<sub>2</sub>.<sup>95</sup> Tanaka *et al.*<sup>96</sup> reported achieving the photocatalytic selective reduction of NO with NH<sub>3</sub> using TiO<sub>2</sub> under xenon lamp illumination at conversion temperatures as low as 50 °C. They also investigated the activity of TiO<sub>2</sub> surfaces loaded with 1 wt% of various transition metal oxides.<sup>97</sup> Their findings revealed that Nb, Mo, and W oxides promoted the photo-SCR activity of TiO<sub>2</sub>, with WO<sub>3</sub>/TiO<sub>2</sub> exhibiting the highest activity (Fig. 5b). The number of acidic sites on TiO<sub>2</sub> as active sites for the photo-SCR reaction determines the reactivity of the photocatalyst.<sup>98</sup> Modification of TiO<sub>2</sub> with WO<sub>3</sub> resulted in increased polarizability, enhancing the surface acidity and thus facilitating the reduction of NO.<sup>99,100</sup> Subsequent studies concluded that agglutination occurs with increasing WO<sub>3</sub> addition, with isolated W species enhancing the chemical reduction activity of NO, while agglutinated W species remain inactive.<sup>101</sup>

**Fig. 4** (a) Photocatalytic conversion of NO to  $N_2$  and  $O_2$  over 1% Fe-doped  $TiO_2$ . The sample was irradiated with UV light, and the target pollutant was 100 ppm NO in He. (b) Possible elementary reaction routes of NO on Fe-doped  $TiO_2$ .<sup>82</sup> (c) Formation of photocatalytic NO decomposition products on SBNO and SBNO-UT, respectively, in a sealed system with 13.5 ppm NO. (d) *In situ* FTIR spectra of SBNO-UT during the photocatalytic NO abatement (0–20 min). The background was collected after the equilibrium of NO adsorption was reached but before illumination. (e) Possible mechanism of the photocatalytic NO decomposition on SBNO-UT.<sup>84</sup>

Perovskite ( $ABO_3$ ) structured materials with flexible structures have recently garnered scientific interest for their application in photo-SCR. Researchers have synthesized Ce–Fe–Mn doped  $CaTiO_3$  perovskite from titanium-containing solid waste using the molten salt method.<sup>103</sup> Fig. 5c–e illustrate that  $CaTiO_3$  showed no photocatalytic activity for NO removal at temperatures ranging from 100 to 300 °C. However, (Ca, Ce) (Ti, Mn, Fe)  $O_3$  demonstrated almost 100% NO conversion under light irradiation at 135 °C ( $GHSV = 72\,000\ h^{-1}$ ). Both Mn and Fe are incorporated into the B-site of  $CaTiO_3$ , while Ce occupies the A-site. Mn doping enhances material light absorption and the capacity to capture NO. After Fe doping, the oxidation center for NO-to- $NO_3^-$  shifts from the five-coordinated  $Mn_{5c}$  site to the  $Fe_{5c}$  site, significantly altering the reaction pathway of conventional SCR. Furthermore, Pr doping of  $LaCoO_3$  supported on a natural palygorskite (Pal) surface eliminates over

95% of  $NO_x$  within the low-temperature range of 150–250 °C.<sup>104</sup> Appropriate Mn doping into  $LaFeO_3$  to form  $LaFe_{1-x}Mn_xO_3$ /attapulgite (ATP) nanocomposites extends its visible light absorption range, resulting in increased NO conversion, reaching a maximum of 85%, with  $N_2$  selectivity close to 100%.<sup>87</sup> Ni-doped  $LaFeO_3$  nanocomposites exhibit a higher  $NO_x$  conversion rate of 92%.<sup>105</sup> Moreover, nitrogen-doped carbon quantum dot modified  $PrFeO_3$ /Pal, with abundant acid sites, demonstrate 93% NO removal and 100%  $N_2$  selectivity under visible light illumination, showing considerable tolerance to  $SO_2$  and  $H_2O$ .<sup>106</sup>

## 4 $NO_x$ upcycling to ammonia

The upcycling of  $NO_x$  to ammonia presents an environmentally friendly opportunity for both  $NO_x$  pollutant elimination and

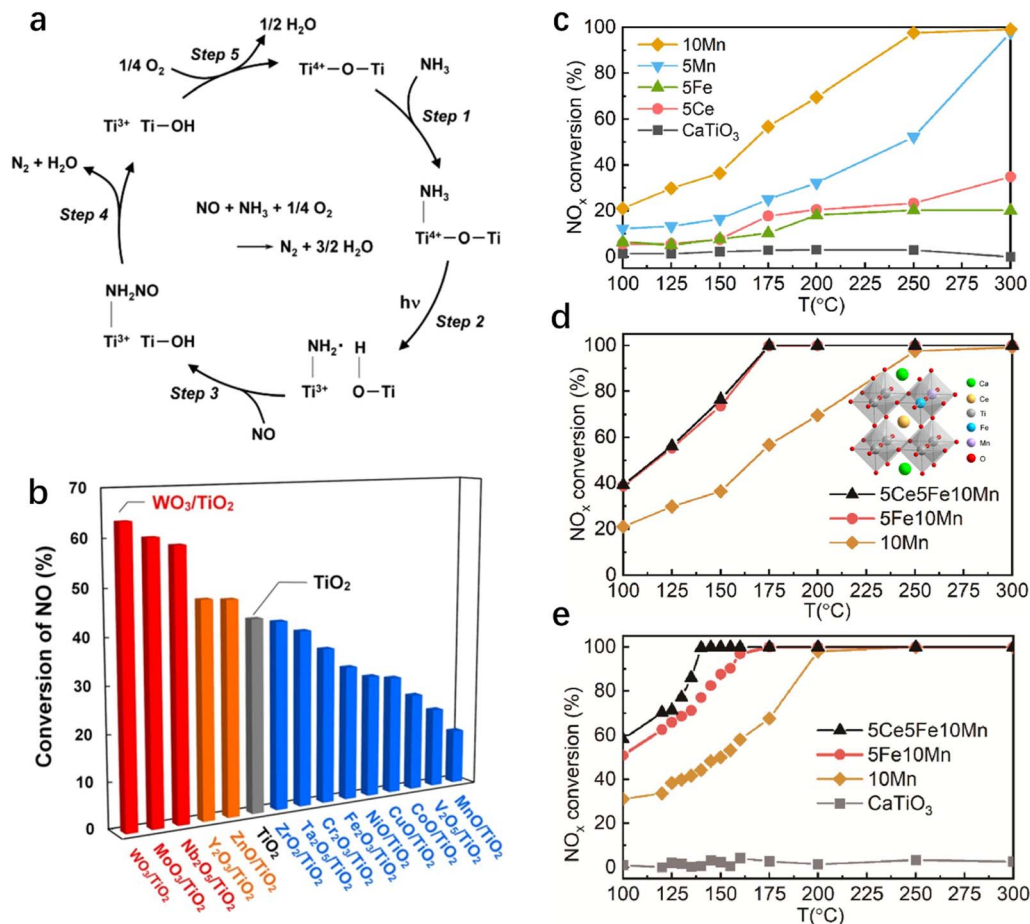

Fig. 5 (a) Proposed reaction mechanism of the photo-SCR over a TiO<sub>2</sub> photocatalyst under UV-light irradiation.<sup>89</sup> (b) Conversion of NO in the photo-SCR over various metal oxide-promoted TiO<sub>2</sub> photocatalysts.<sup>102</sup> (c–e) NH<sub>3</sub>-SCR activity of single- and multi-element doped CaTiO<sub>3</sub>.<sup>103</sup>

sustainable ammonia production. While electrocatalytic synthesis of ammonia has garnered considerable attention, photocatalytic reduction of NO to ammonia remains in its nascent stage. Nevertheless, recent years have seen significant advancements in photocatalytic ammonia synthesis. The authors outline two potential approaches for NO<sub>x</sub> resource utilization *via* photocatalysis. One method involves the use of a chelating agent with the dissolution of NO in water, followed by a one-step reduction to ammonia *via* photocatalysis (one-step method). Another approach entails oxidizing NO to the highly water-soluble NO<sub>3</sub><sup>-</sup> initially, followed by its reduction to ammonia through an eight-electron reduction process (two-step method).

#### 4.1 One-step method (NO → NH<sub>3</sub>)

The direct one-step synthesis of NH<sub>3</sub> from NO is an ideal strategy for transforming waste into valuable resources. While research efforts in NO<sub>x</sub> reduction reactions (NO<sub>x</sub>RR) have predominantly focused on enhancing NH<sub>3</sub> synthesis rates, achieving high NO<sub>x</sub> conversion efficiency remains a crucial yet less explored objective.<sup>107,108</sup> Typically, NO<sub>x</sub>RR experiments necessitate efficiency tests with high concentrations (>10 000 ppm) of NO to ensure an adequate feedstock for enhancing

ammonia production.<sup>109</sup> However, limited NO conversion persists as a key challenge for the sustainability of the NO-to-NH<sub>3</sub> reduction pathway.

The ultra-low solubility of NO in water (1.94 mmol L<sup>-1</sup>) is one of the primary reasons for limited NO conversion.<sup>110</sup> To address this challenge, a novel one-step NO<sub>x</sub> photoreduction pathway, referred to as the on-site coupling system, has been recently developed. This system enables NO direct upcycling under ambient conditions (Fig. 6a).<sup>111</sup> Specifically, the solution was supplemented with Fe(II)EDTA as a NO chemical absorbent, generating Fe(II)EDTA-NO chelates, while formaldehyde (HCHO) served as an antioxidant to prevent the Fe(III) formation from Fe(II) oxidation. This simultaneous chemical absorption and photocatalytic reduction system enabled continuous NO adsorption, NO reduction, and Fe(II)EDTA regeneration on-site.<sup>111</sup> TiO<sub>2</sub> decorated with 11.6 mg L<sup>-1</sup> Au nanoparticles could provide ample active sites to facilitate charge separation, thereby enhancing NH<sub>4</sub><sup>+</sup> generation. Using this on-site coupling system, the performance of Au<sub>NPs</sub>-TiO<sub>2</sub> is shown in Fig. 6b and c, demonstrating exceptional NO conversion efficiency (89.0%), ammonia production selectivity (95.6%), and ammonia recovery efficiency (>90%). Virtually no other side products are detected. Subsequently, the generated ammonia was recovered *via*

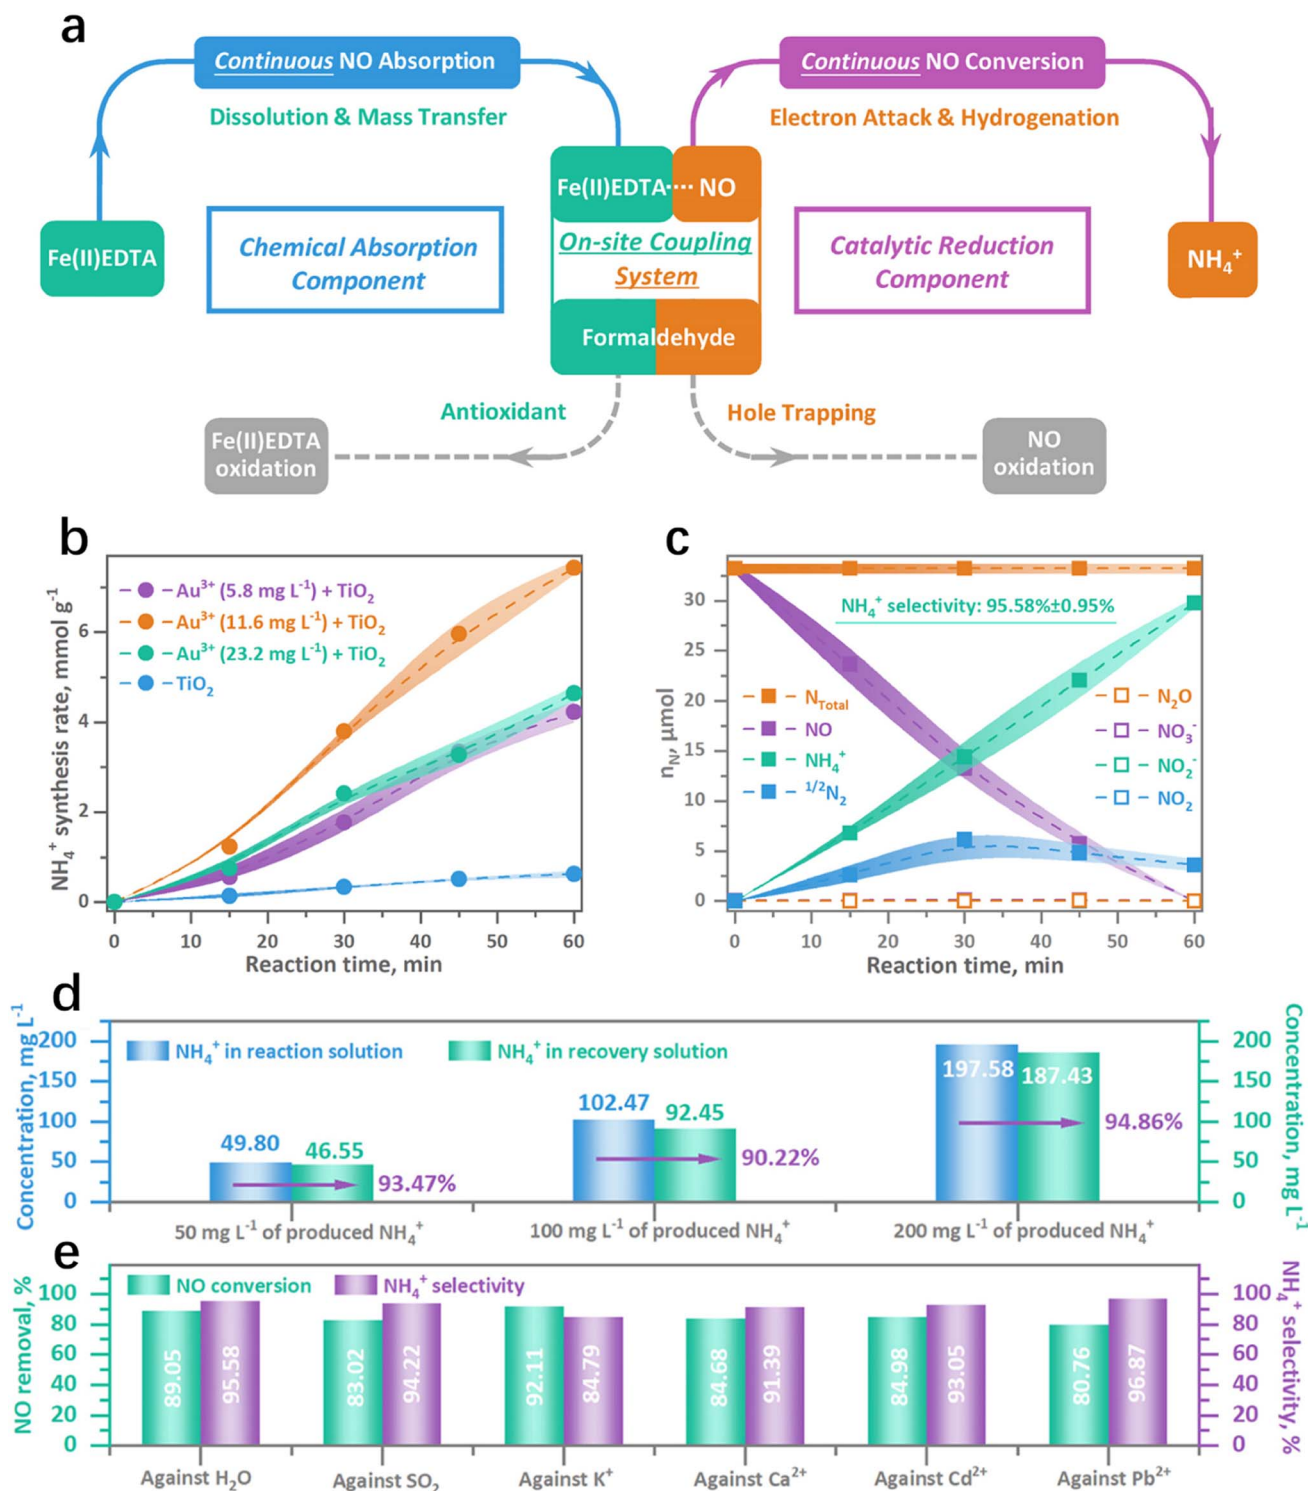

Fig. 6 (a) Illustration of the on-site coupling system of continuous chemical absorption and catalytic reduction. (b)  $\text{NH}_4^+$  synthesis rate between the pristine and Au-decorated  $\text{TiO}_2$ . (c) Selectivity test. (d) Ammonia recovery evaluation after the continuous absorption and photoreduction of NO. (e) Poisoning resistance against vapor,  $\text{SO}_2$ , and metals.<sup>111</sup>

a simple ion exchange method, with recovery rates still exceeding 90% within 50–200  $\text{mg L}^{-1}$  ammonia production (Fig. 6d). Moreover, the NO conversion efficiency and the  $\text{NH}_4^+$  selectivity remained unaffected even in the presence of resistance factors such as  $\text{H}_2\text{O}$ ,  $\text{SO}_2$ , and metal ions ( $\text{K}^+$ ,  $\text{Ca}^{2+}$ ,  $\text{Cd}^{2+}$ ,

and  $\text{Pb}^{2+}$ ) (Fig. 6e). These high recovery efficiencies and anti-poisoning capacities underscore the environmental practicality of  $\text{NO}_x$  removal in flue gas. The on-site coupling strategy achieves significant efficiency milestones for sustainable NO

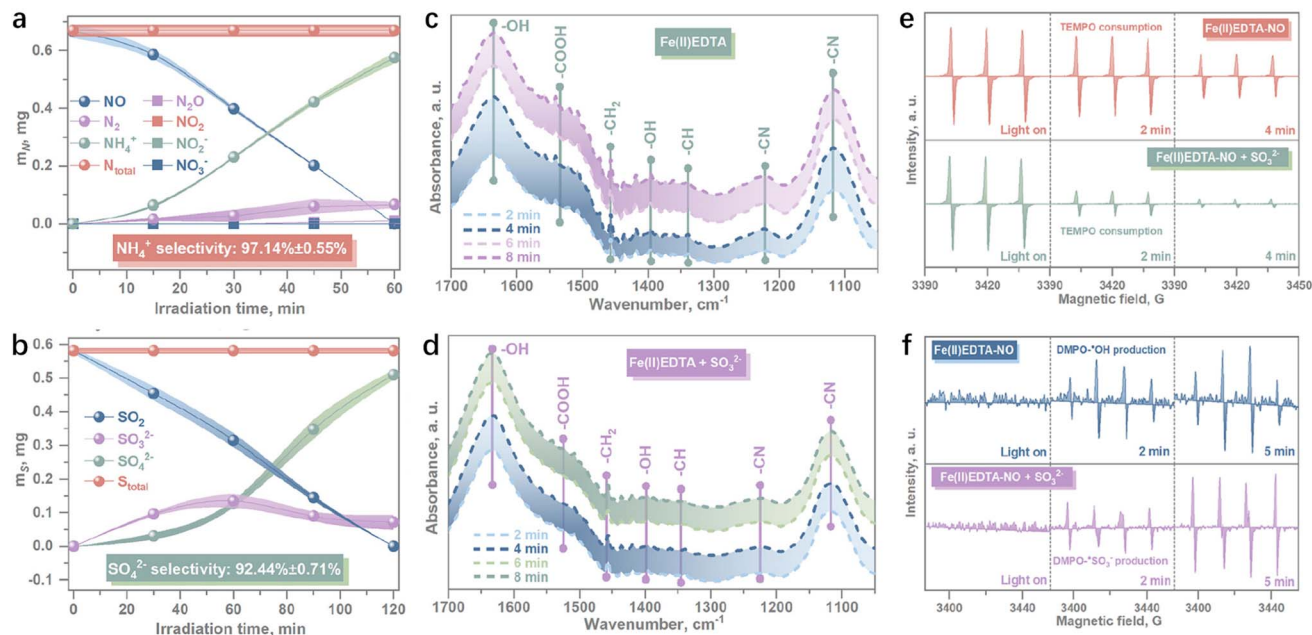

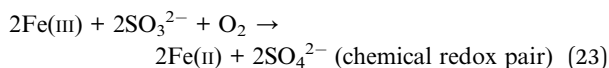

Fig. 7 The continuous selectivity evaluation for (a) NO-to-NH<sub>3</sub> reduction and (b) SO<sub>2</sub>-to-SO<sub>4</sub><sup>2-</sup> oxidation. *In situ* ATR-FTIR spectra for the recording of Fe(II)EDTA characterization signals (c) without and (d) in the presence of SO<sub>3</sub><sup>2-</sup> provision. (e) *In situ* EPR measurements for the consumption of TEMPO in the photocatalytic reduction process of NO without (up) and with (down) SO<sub>3</sub><sup>2-</sup> provision, respectively, (f) *In situ* EPR measurements for the production of DMPO·OH by H<sub>2</sub>O oxidation (up) and DMPO·SO<sub>3</sub><sup>·-</sup> by SO<sub>3</sub><sup>2-</sup> oxidation (down), respectively.<sup>114</sup>

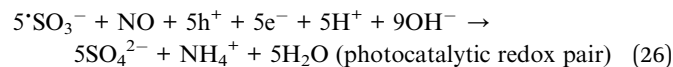

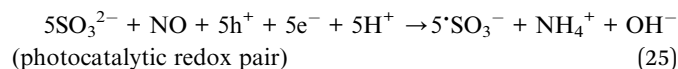

removal and also offers insights into NO upcycling for the future of carbon neutrality.

The simultaneous presence of NO and SO<sub>2</sub> in flue gas poses significant challenges for their concurrent removal and recovery.<sup>112,113</sup> Since SO<sub>2</sub> is easily dissolved and oxidized, it can serve as a potential reductant in the NO photoreduction reaction. Furthermore, the on-site coupled system demonstrated the synergistic removal and recycling of NO and SO<sub>2</sub> without the need for scavengers.<sup>114</sup> The formation of the SO<sub>2</sub>-NO redox pair facilitates high conversion rates of both NO and SO<sub>2</sub> in continuous flow. Achieving a remarkable selectivity for both NO-to-NH<sub>3</sub> upcycling (97%) and SO<sub>2</sub>-to-SO<sub>4</sub><sup>2-</sup> purification (92%) simultaneously underscores the practicability of value-added conversion of air pollutants (Fig. 7a and b).<sup>114</sup> Maintaining the efficiency of NO conversion and reduction crucially depends on preventing the oxidation of Fe(II) to Fe(III) in Fe(II)EDTA. Through verified *in situ* ATR-FTIR experiments, it was revealed that SO<sub>2</sub> exhibited a promoting effect on Fe(II) maintenance, while no interaction was observed between SO<sub>2</sub> and EDTA (Fig. 7c and d).

The chemical redox pair of SO<sub>2</sub>-Fe(III) is illustrated in eqn (21)–(23).<sup>114</sup>

As depicted in Fig. 7e and f, compared to h<sup>+</sup>-induced ·OH production, the h<sup>+</sup>-induced SO<sub>2</sub> oxidation reaction to ·SO<sub>3</sub><sup>-</sup> promotes charge separation, thereby generating more e<sup>-</sup>, and enhancing the efficiency of the nitrogen oxide reduction reaction to produce NH<sub>3</sub>. The overall mechanism for synchronous NO and SO<sub>2</sub> conversion is illustrated in eqn (24)–(26):

Thus, a one-step NO<sub>x</sub> reduction method has been devised by concurrently absorbing and converting NO<sub>x</sub>. This system also exhibits great resistance to toxicity, including resistance to K<sup>+</sup>, Ca<sup>2+</sup>, and Cd<sup>2+</sup> metal ions, respectively. The effective separation and retrieval of reaction products provide this system with sustainable stability and potential economic viability. Continuous NO<sub>x</sub> removal and upcycling under ambient conditions with high conversion efficiencies were achieved, marking significant advancements in photocatalytic NO<sub>x</sub> removal and recycling compared to SCR and chemical absorption technologies.

#### 4.2 Two-step method (NO → NO<sub>3</sub><sup>-</sup> → NH<sub>3</sub>)

Among the redox products of NO<sub>x</sub>, NO<sub>3</sub><sup>-</sup> is the dominant and accessible substance on the surface of the photocatalyst.<sup>39,67</sup>

Significant quantities of  $\text{NO}_3^-$  are released into the environment through processes such as the combustion of fossil fuels and agricultural activities, driven by the progress of urbanization and industrialization.<sup>115</sup> The surface of the photocatalyst is the overlooked storage site for  $\text{NO}_3^-$ , where the generated nitrate could be easily removed from the catalyst and subsequently concentrated in liquid form.<sup>69,116</sup> However, excessive amounts of  $\text{NO}_3^-$  in water can pose a pollution concern. To address this issue, photocatalytic technologies have been employed to convert excess nitrate into valuable  $\text{NH}_3$ .

Photocatalytic reduction of  $\text{NO}_3^-$  to ammonia *via* multiple electron transfer (eqn (27)), could emerge as a potent method for ammonia production under ambient conditions of room temperature and atmospheric pressure.<sup>117</sup>  $\text{N}_2$  and  $\text{H}_2$  formation reactions are two side reactions that consume photoexcited electrons (eqn (28) and (29)).<sup>117,118</sup> Therefore, it is necessary to enhance not only the ammonia yield but also the ammonia selectivity. A summary of studies on the reduction process of nitrate to ammonia by various photocatalysts is presented in Table 1.

It can be inferred from Table 1 that  $\text{TiO}_2$ -based materials are prominently utilized as catalysts for  $\text{NO}_3^-$ -to- $\text{NH}_3$  reduction, particularly highlighting metal-modified  $\text{TiO}_2$  nanosheets (TNSs). Recently, as shown in Fig. 8a, alkaline-earth oxide clusters constructed on  $\text{TiO}_2$  nanosheets ( $\text{MO}_{\text{NCS}}$ -TNSs,  $\text{M} = \text{Mg}$ ,  $\text{Ca}$ ,  $\text{Sr}$  or  $\text{Ba}$ ) were reported to enhance  $\text{NO}_3^-$ -to- $\text{NH}_4^+$  production, among which  $\text{BaO}_{\text{NCS}}$ -TNSs achieve both exceedingly high  $\text{NH}_4^+$  selectivity (97.7%) and high  $\text{NH}_4^+$  yield ( $89.8 \text{ mmol g}_{\text{cat}}^{-1}$

$\text{h}^{-1}$ ).<sup>121</sup> To the best of our knowledge, this is the highest production of ammonia by the photocatalytic reduction reaction. Remarkably, there's an incremental rise in the rate of ammonia synthesis throughout the reaction, attributed to the concurrent Operando formation of  $\text{BaO}_{\text{NCS}}$  and the ammonia synthesis reaction (Fig. 8b and c). Upon achieving stabilization of  $\text{BaO}_{\text{NCS}}$  on TNSs, a notable and consistent production of ammonia on  $\text{BaO}_{\text{NCS}}$ -TNS composites was realized.

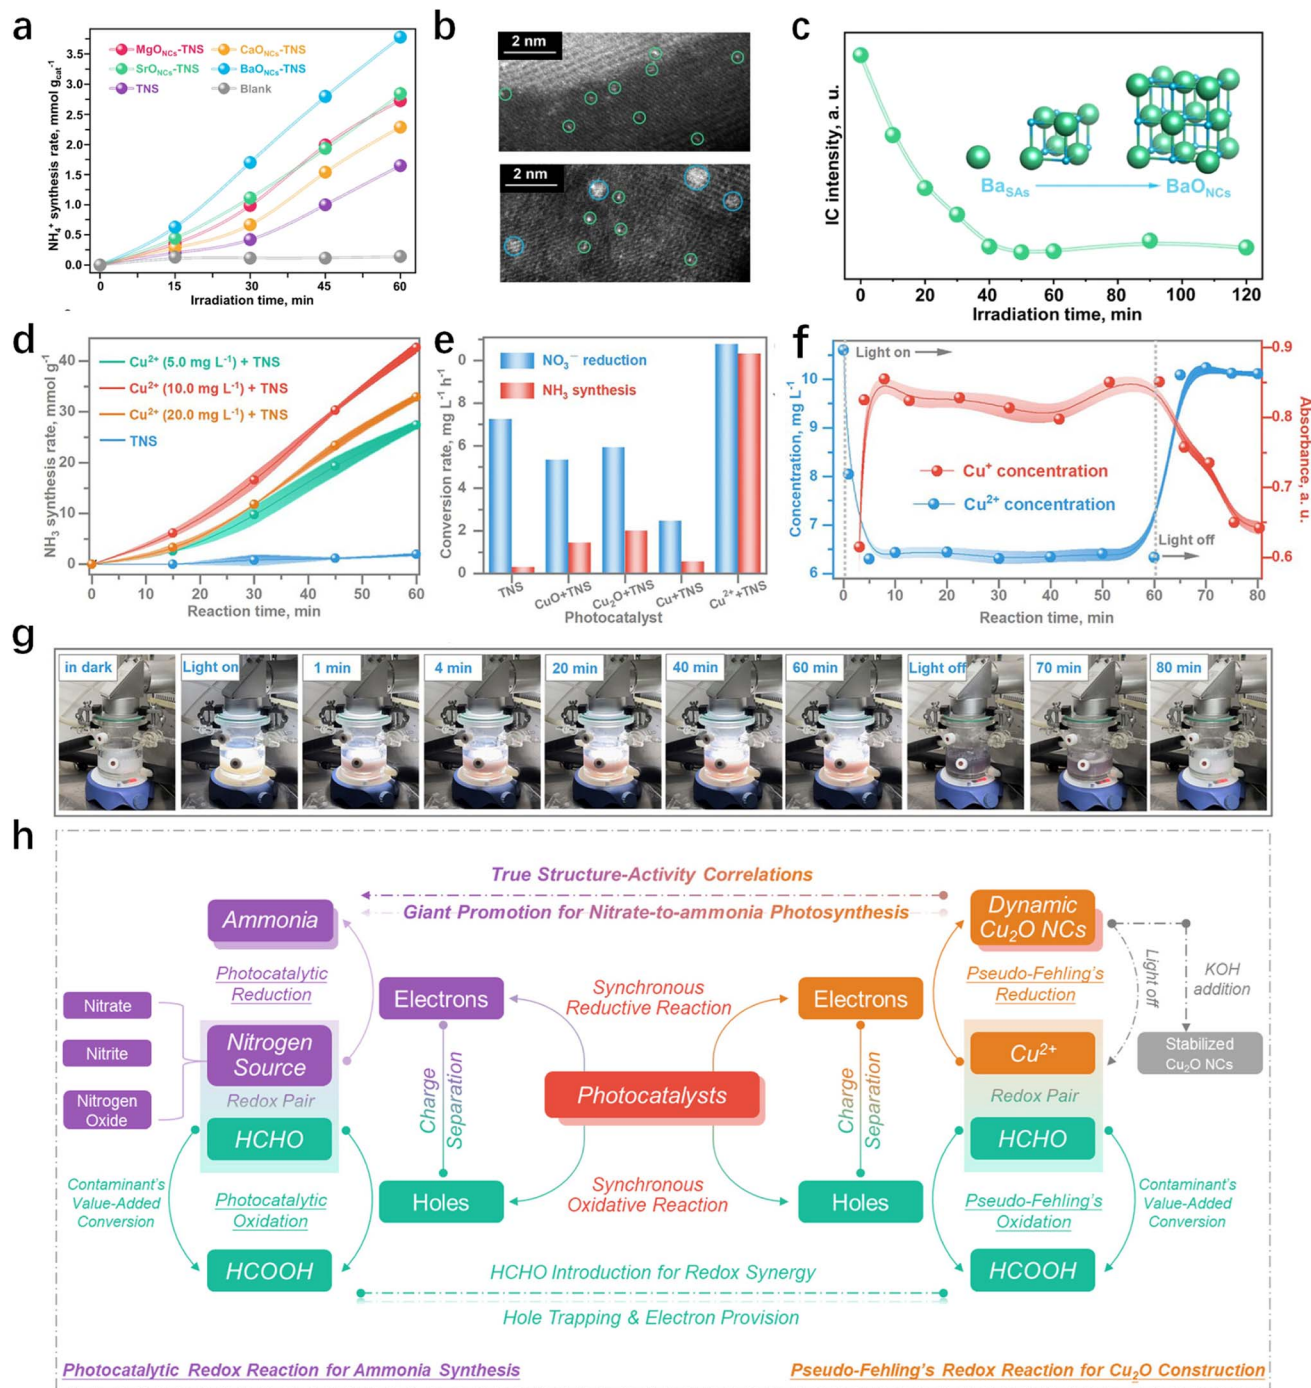

Chen *et al.*<sup>119</sup> further elucidated the criticality of the on-site formation of authentic active sites under realistic catalytic conditions. They engineered  $\text{Cu}_2\text{O}_{\text{NCS}}$ -TNS materials, wherein dynamic  $\text{Cu}_2\text{O}$  sub-nanoclusters were on-site constructed on TNSs using  $\text{CuCl}_2$  solution through a photoinduced pseudo-Fehling's route. Different from  $\text{BaO}_{\text{NCS}}$ -TNS which remains stable once it has been constructed, the morphology and chemical state of  $\text{Cu}_2\text{O}$  exhibit dynamic evolution, as the actual reaction cannot progress over preformed  $\text{Cu}_2\text{O}$  sites (Fig. 8d and e). Numerous *in situ* experiments revealed a photoswitchable reversible conversion pattern between  $\text{Cu}^{2+}$  and  $\text{Cu}^+$  in the photosynthesis reaction, aligning with the performance of ammonia synthesis by nitrate reduction (Fig. 8f and g).<sup>119</sup>  $\text{NH}_3$  photosynthesis was directly attributed to the enhanced charge separation and transformation capacity from the  $\text{Cu}_2\text{O}$  active sites. Consequently, the establishment of a genuine structure-activity correlation was achieved by uncovering the synchronous formation of the  $\text{Cu}_2\text{O}$  active site and catalytic reaction (Fig. 8h).

In addition, a groundbreaking perspective has emerged regarding the interplay between single atoms and oxygen vacancies (OVs) (Fig. 9).<sup>118</sup> The incorporation of single-atom Cu into  $\text{TiO}_2$  nanosheets (Cu-TNSs) resulted in a 62-fold increase in ammonia production compared to pristine  $\text{TiO}_2$ , with a selectivity of 97.6%. The introduction of Cu atoms, replacing Ti sites, induces the generation of OVs and lattice strain.  $\text{NO}_3^-$  preferentially adsorbs onto Ti atoms neighboring Cu atoms. The near-isolated Cu atoms and OVs facilitate multiple  $\text{NO}_3^-$  adsorptions at a single site, effectively inhibiting the release of  $\text{NO}_2^-$

Table 1 Comparison of the results of  $\text{NH}_3$  production with different photocatalysts

intermediates and minimizing N-to-N interactions, thus ensuring high  $\text{NH}_3$  selectivity.

Furthermore,  $\text{CuO}_x\text{@TNS}$  was designed for  $\text{NO}_3^-$  reduction with a 100%  $\text{NO}_3^-$  conversion rate and 96.1% ammonia

selectivity by coupling the nitrate reduction reaction with a glycol oxidation reaction system.<sup>120</sup> The active site for improving ammonia formation is identified as the  $\text{CuO}_x$  species with an amorphous Cu–O–Ti bimetallic oxide cluster structure

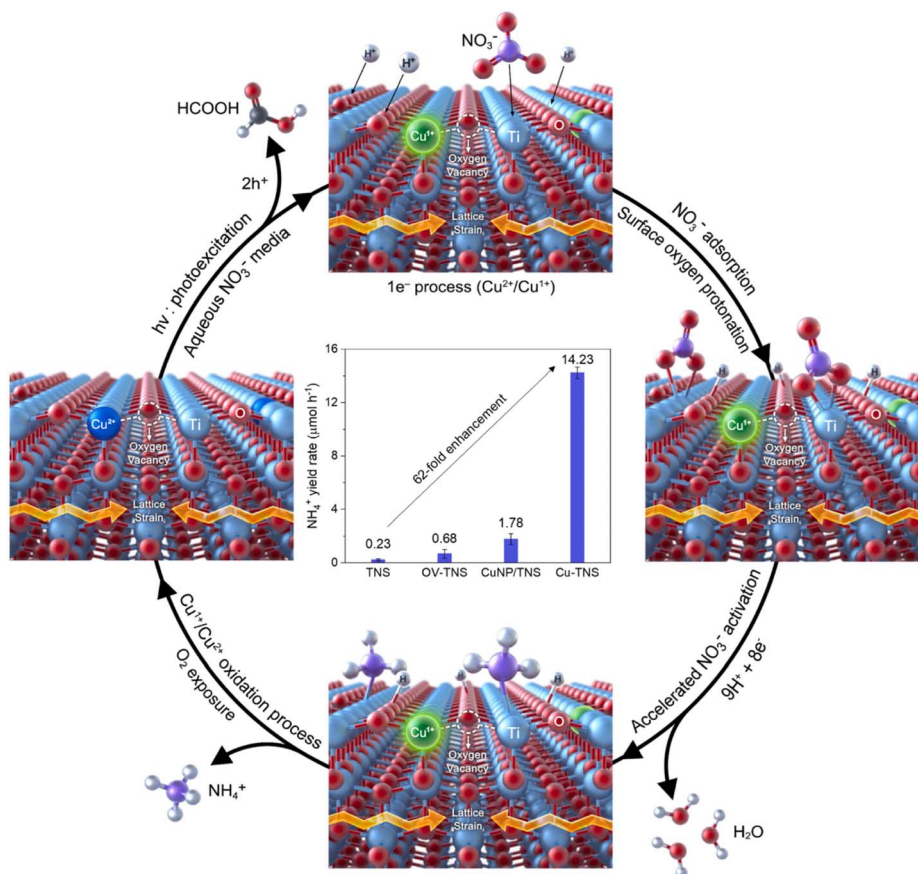

Fig. 9 NO<sub>3</sub><sup>-</sup>-to-NH<sub>3</sub> reaction mechanism on Cu-TNSs. TiO<sub>2</sub> with isolated Cu<sup>2+</sup> atomic sites (blue) and defects generates photoexcited electrons and holes under light irradiation.<sup>118</sup>

(Fig. 10a).<sup>120</sup> Given that redox reactions occur concurrently, it's evident that the oxidation half-reaction also significantly influences NH<sub>3</sub> production. To explore the impact of various oxidation half-reactions on NO<sub>3</sub><sup>-</sup> reduction, oxidative reactants including deionized water (DI), methanol (CH<sub>3</sub>OH), ethylene glycol ((CH<sub>2</sub>OH)<sub>2</sub>), and acetic acid (HCOOH) are introduced into the reaction system (Fig. 10b and c). It is revealed that the NO<sub>3</sub><sup>-</sup> reduction process is hindered by the formation of potent oxidizing ·OH radicals (Fig. 10d). The presence of ethylene glycol expedites the consumption of h<sup>+</sup> during the formation of alkoxy radicals (·R), thus mitigating ·OH production. Moreover, the Cu–O–Ti sites could promote the preferential oxidation of ethylene glycol, thereby enhancing both the efficiency and selectivity of ammonia production (Fig. 10e). These findings underscore the pivotal role of the oxidation half-reaction. The deliberate design of the oxidation half-reaction not only enhances the effective utilization of electrons and holes but also modulates the reaction pathway, thus promoting the progress of the NO<sub>3</sub><sup>-</sup> reduction half-reaction.

In summary, the photocatalytic performance of NO<sub>3</sub><sup>-</sup>-to-NH<sub>3</sub> photocatalytic reduction highly relies on the strategic construction of active sites and the coordination of redox reactions. This offers an innovative perspective on experimental design aimed at achieving high NH<sub>3</sub> selectivity and production.

Recent studies have shown that NO<sub>3</sub><sup>-</sup> originating from NO oxidation has achieved nearly 100% NH<sub>3</sub> selectivity. It is desired to employ a two-step process (NO → NO<sub>3</sub><sup>-</sup> → NH<sub>3</sub>) to achieve a highly selective conversion of NO to NH<sub>3</sub>.

## 5 Conclusions and perspectives

### 5.1 Conclusions

Table 2 summarizes and compares the application scenarios, reaction conditions, photocatalysts, and reaction activity for NO<sub>x</sub> removal under the different reaction pathways. It is found that the application of photocatalytic technology has transcended indoor NO<sub>x</sub> treatment and is now addressing challenges posed by complex pollutant compositions and industrial flue gases. Interestingly, TiO<sub>2</sub> remains the most extensively studied photocatalyst in both NO<sub>x</sub> oxidation and NO<sub>x</sub> reduction, probably due to its outstanding carrier separation capability. Besides, the overall redox properties also depend on catalyst modification or adjustment of environmental atmospheres in different systems. The photocatalytic performance showed that the NO<sub>x</sub> conversion and product selectivity have exceeded 90% for most of the redox pathways except NO<sub>x</sub> decomposition. This marks a significant advancement towards the future application of photocatalytic NO<sub>x</sub> removal and recovery.

NH<sub>3</sub> photosynthesis yields under different cooperative oxidative half-reactions for (b) TNSs and (c) 0.52 wt% CuO<sub>x</sub>@TNS after 1 h irradiation. (d) EPR spectra of DI, CH<sub>3</sub>OH, (CH<sub>2</sub>OH)<sub>2</sub>, and HCOOH oxidative half-reactions on TNSs and 0.52 wt% CuO<sub>x</sub>@TNS catalyst after light irradiation for 5 min. (e) Illustration of the directed NO<sub>3</sub><sup>-</sup>RR by coordination of different oxidative reactions.<sup>120</sup>

In conclusion, photocatalytic technology is a promising method for NO<sub>x</sub> removal and recovery, owing to its mild reaction conditions and eco-friendliness. In recent years, significant strides have been made in the field of photocatalytic NO<sub>x</sub> removal, spanning from the optimization of photocatalysts to the exploration of mechanisms and the modulation of reaction pathways, resulting in unprecedented performance in NO<sub>x</sub> removal. The emerging photocatalytic reduction of NO<sub>x</sub> to ammonia offers a viable alternative for NO<sub>x</sub> recovery. This review summarizes the latest advancements in photocatalytic removal, encompassing NO<sub>x</sub> oxidation (both single and synergistic removal, as well as NO<sub>3</sub><sup>-</sup> decomposition), NO<sub>x</sub> reduction to nitrogen, and the upcycling of NO<sub>x</sub> into ammonia.

Furthermore, we highlight photocatalysis-based NO<sub>x</sub> recovery, including one-step and two-step methods, as a promising approach to tackle existing environmental and energy challenges.

## 5.2 Future outlook

The utilization of photocatalytic technology for the removal and recovery of NO<sub>x</sub> is currently in the research phase, with the practical application still a considerable distance away. We recommend that future studies systematically address the following issues:

(1) Comparing the performance of photocatalysts across different studies in the realm of NO<sub>x</sub> oxidation proves

Table 2 Conclusion and comparison of NO<sub>x</sub> removal by various reaction pathways

Reaction pathway	Product	Scenarios of application	Typical photocatalysts	NO <sub>x</sub> concentration	Temperature (°C)	Flow rate (L min <sup>-1</sup> )/GHSV (h <sup>-1</sup> )	Carrier gas	Supplements	Conversion (%)	Selectivity (%)
NO <sub>x</sub> oxidation	NO <sub>3</sub> <sup>-</sup>	Air purification	TiO <sub>2</sub> , g-C <sub>3</sub> N <sub>4</sub> , WO <sub>3</sub> , Bi-based materials	~600 ppb	Room temperature	1 L min <sup>-1</sup>	Air	N/A	~90	~97
NO <sub>x</sub> reduction	NO <sub>3</sub> <sup>-</sup>	Air purification	TiO <sub>2</sub> , In(OH) <sub>3</sub> , Sr <sub>2</sub> Sb <sub>2</sub> O <sub>7</sub>	30 ppm	Room temperature	1 L min <sup>-1</sup>	Air	VOCs, SO <sub>2</sub>	~100	N/A
	N <sub>2</sub>	Air purification	TiO <sub>2</sub> , g-C <sub>3</sub> N <sub>4</sub>	<1 ppm	N/A	1 L min <sup>-1</sup>	Air/Ar	N/A	~50	N/A
NO <sub>x</sub> upcycling	N <sub>2</sub>	Flue gas treatment	TiO <sub>2</sub> , perovskite	1000 ppm	<200	50 000 h <sup>-1</sup>	3% O <sub>2</sub> , 97% N <sub>2</sub>	NH <sub>3</sub> , H <sub>2</sub> , hydrocarbon, etc.	>90	~100
	NH <sub>3</sub>	Flue gas treatment	TiO <sub>2</sub>	500 ppm	25	25 000 h <sup>-1</sup>	N/A	Fe(II)EDTA/hole scavengers (e.g. HCHO, SO <sub>2</sub> )	97.6	~97.1%

challenging due to the diverse array of reaction conditions such as light source, gas flow rate, initial NO<sub>x</sub> concentration, mass of the photocatalyst, reactor design, and others. To comprehensively evaluate photocatalyst performance and identify truly efficient photocatalysts, there is a pressing need to establish uniform performance standards.

(2) Despite notable advancements in the performance of photocatalytic NO<sub>x</sub> removal in recent years, a gap persists when compared to thermal catalytic NO<sub>x</sub> removal. One of the primary reasons for this gap is the insufficient exploration of the interfacial reaction mechanism governing photocatalytic NO<sub>x</sub> removal. To address this, *in situ* detection methods with higher resolution, such as *in situ* EPR, DRIFTS, and Raman spectroscopy, should be more extensively employed. These techniques can unveil the intricacies of the photocatalytic reaction mechanism, subsequently informing catalyst design and modification efforts.

(3) In the one-step method, the yield of ammonia is significantly influenced by the solubility of NO, thus necessitating further enhancement of NO solubility in water. Introducing chemical absorbents to adsorb NO suggests the need for additional methods to separate the resulting ammonia, thereby increasing costs and rendering it less favorable for practical applications. An absorbent-free approach is preferable to augment the solubility of high concentrations of NO in water and to develop photocatalysts capable of achieving an ammonia yield that meets recovery criteria. Moreover, photocatalysts can be selectively designed to further reduce NO<sub>x</sub> to N<sub>2</sub> instead of ammonia, offering an alternative solution to address current environmental challenges.

(4) In the two-step process, the primary challenge lies in effectively collecting the nitrates produced from NO<sub>x</sub>. During the photocatalytic NO<sub>x</sub> oxidation process, nitrates gradually accumulate on the catalyst surface. However, due to the limited availability of adsorption sites on the surface and the simultaneous decomposition of nitrates, only a small portion of nitrates remains on the photocatalyst surface. It is imperative to enhance the thorough oxidation of NO<sub>x</sub> and suppress the decomposition of nitrates. Additionally, nitrates are commonly found in relatively high concentrations in wastewater, presenting an opportunity to enhance ammonia production.

(5) Machine learning offers a potent tool for predicting catalytic reaction performance accurately, aiding chemists in tasks like material screening, experiment optimization, and mechanistic studies. Nonetheless, it's crucial to emphasize that machine learning should be applied judiciously. While it's a valuable tool, it's not a universal solution and cannot substitute well-considered experimental designs. In practice, a combination of expertise is still vital to ensure that machine learning and traditional methods work together harmoniously to achieve broader environmental science objectives.
