Addressing main challenges in the tertiary treatment of urban wastewater: are homogeneous photodriven AOPs the answer?

Luigi Rizzo 

Homogeneous photodriven advanced oxidation processes (HP-AOPs) have been increasingly investigated in past years as a possible alternative solution to conventional tertiary treatment methods of urban wastewater. Despite the encouraging results in successfully addressing some of the main challenges, such as pathogen inactivation, removal of contaminants of emerging concerns (CECs), and antibiotic resistance (AR) control, their full-scale application is still poor. In this review, the main challenges in the tertiary treatment of urban wastewater are identified and the advances of HP-AOPs in addressing such challenges are critically discussed, emphasizing the respective advantages and drawbacks, even compared to consolidated tertiary treatment methods. Differences between solar- and UV-driven HP-AOPs, acidic vs. neutral pH photo-Fenton, as well as between homogeneous and heterogeneous photodriven AOPs are also analyzed and critically discussed. An approach for selecting model pollutants (e.g., CECs, pathogens, and AR indicators) as well as to validate under realistic conditions the results achieved under controlled laboratory conditions is also recommended. The most relevant issues and gaps in the knowledge are identified and discussed. A large number of investigations available in the scientific literature strongly support the capacity of HP-AOPs to effectively address the challenges in the tertiary treatment of urban wastewater, and the time for their full-scale application is almost mature. While the UV/H₂O₂ process is already applied as a final step in potable water reuse treatment trains, solar photo-Fenton has been quite exhaustively and successfully investigated in the tertiary treatment of urban wastewater so far and it is expected to be implemented at full scale in raceway pond reactors. In conclusion, 10 recommendations to take into account when designing the experimental plan are provided. Hopefully, this manuscript is also useful to water professionals and managers to learn possible effective and sustainable alternatives to conventional processes.

Water impact

Urban wastewater treatment plants (WTPs) are the main hotspots for the release of contaminants of emerging concern into the environment and determinants of antibiotic resistance. Homogenous photodriven advanced oxidation processes are among the most investigated and potentially successful solutions to address such challenges. Their investigation as tertiary treatment processes in WTPs is critically reviewed and recommendations to improve the experimental design and accelerate their full-scale application are provided.

1. Introduction

Synthetic or natural chemicals such as active ingredients of pharmaceuticals and personal care products, pesticides, and flame retardants, also grouped as contaminants of emerging concern (CECs), are being continuously released in the environment.¹ Though some of them occur at low concentrations in freshwater and wastewater (in the range of ng L⁻¹–μg L⁻¹), they still result in toxic effects.^{1,2} Moreover,

among pharmaceuticals, the occurrence of antibiotics in the environment is a reason of further concern due to their contribution to the spread of antibiotic resistance (AR).^{3,4} In addition to such pollutants of concern, microplastics also result in a serious threat to the environment.⁵ Urban wastewater treatment plants (WTPs) are among the main hotspots for the release of all these pollutants into the environment because, due to the lack of specific regulations in most countries, they are not designed to specifically remove them.⁶ To improve the removal of such pollutants, most existing WTPs should be upgraded and new WTPs should be designed with proper (tertiary) treatment methods. While microplastics can be effectively removed through

(advanced) separation methods,⁷ for CECs and AR determinants, such as antibiotic-resistant bacteria (ARB) and genes (ARGs), separation and biological processes are poorly effective or completely ineffective;^{6,8} thus, other solutions should be investigated and implemented. Advanced oxidation processes (AOPs) have been widely and successfully investigated at the lab and pilot scale, in the removal of most CECs⁶ as well as in the inactivation of ARB and ARGs,⁹ in particular, the so-called homogenous photodriven AOPs (HP-AOPs). HP-AOPs have attracted increasing interest from the scientific community because they are more effective than other AOPs in the removal of the abovementioned pollutants and potentially easy to upscale.⁶ However, these processes are not yet applied at the full scale because of the lack of specific regulations on CECs (except Switzerland), as well as ARB and ARGs that do not make HP-AOPs economically competitive with conventional tertiary treatment methods. However, the increasing interest and awareness about the risk related to their release into the environment has brought the problem to the attention of the competent authorities, which in some cases have taken the action of monitoring specific contaminants (such as in Europe with the EU watch list (WL)¹⁰), suggesting a forthcoming regulation. A positive step in this direction at the European level comes from the recent approval of the first EU regulation on wastewater reuse (Regulation 2020/741).¹¹ It will come in force in the EU countries on June 2023, and the relevant stakeholders are expected to finalize a risk assessment plan where the CECs, AR determinants, and microplastics, among other pollutants, should also be taken into account. If one or more of the corresponding indicators should be higher than the respective risk threshold value, the WTP should be upgraded or designed accordingly.

Luigi Rizzo

Luigi Rizzo is Associate Professor in Sanitary and Environmental Engineering at University of Salerno (Italy). He is Coordinator of the “International PhD School on Advanced Oxidation processes”, external expert of European Commission Committees, editor of “Water Science and Technology” journal, and associate editor of the “Journal of Environmental Chemical Engineering”. His main research interest is water/

wastewater treatment by advanced oxidation processes (AOPs). He has published 150 papers (107 in peer-reviewed and indexed journals) (8100 citations and 45 h-index in SCOPUS). He was ranked 82th (out of 77304) in the category Environmental Science according to Stanford’s “Top 100 000 Scientists (2020)” list.

In this review paper, HP-AOPs and challenges in the tertiary treatment of urban wastewater are first introduced (in chapters 2 and 3, respectively). Subsequently, the advances in the investigation of HP-AOPs application to urban wastewater treatment in addressing such challenges are critically discussed (chapter 4), emphasizing the respective advantages and drawbacks, even compared to consolidated tertiary treatment methods (chapter 7). A focus on specific issues including differences between solar and UV driven HP-AOPs (chapter 5), acidic vs. neutral pH photo-Fenton process (paragraph 4.1.1), as well as between homogeneous and heterogeneous photodriven AOPs (chapter 6) are also analyzed and critically discussed. An approach for selecting the model pollutants (*e.g.*, CECs, pathogens, and AR indicators) as well as to validate under realistic conditions results achieved under controlled laboratory conditions is recommended (paragraph 3.7). A comparison among tertiary treatment methods under realistic conditions and different end-points as well as respective advantages and drawbacks are discussed and summarized (chapter 8). Finally, 10 recommendations to take into account when designing the experimental plan are provided (chapter 9).

2. Homogeneous photodriven advanced oxidation processes (HP-AOPs)

AOPs produce highly oxidizing species, including reactive oxygen species (ROS) and radicals, which are among the most powerful substances that can degrade organic pollutants, oxidize inorganic species, and inactivate several microorganisms. AOPs include homogeneous (*e.g.*, UV/H₂O₂, Fenton, photo Fenton, ozonation, and UV/Cl₂) and heterogeneous (solid semiconductors + light source, such as UV/TiO₂ and heterogeneous photo-Fenton) processes. Among homogeneous processes, HP-AOPs have attracted increasing interest from the scientific community due to their efficiency in the removal of several contaminants and inactivation of microorganisms as well as their potential for short-term application at full scale as tertiary treatment methods of urban wastewater.⁶ In the following paragraphs, the most investigated HP-AOPs are briefly introduced.

2.1 Photo-Fenton and photo-Fenton-like processes

Fe(III) hydroxy complexes such as Fe(OH)²⁺ and Fe₂(OH)₂⁴⁺, which occur in aqueous solutions under acidic pH conditions, absorb light in the UV and the visible regions. In particular, Fe(OH)²⁺, the most important species, results in the formation of Fe²⁺ and hydroxyl radical (HO[•]), according to the following reaction.¹²

The reduced iron can react with H_2O_2 to produce HO^\cdot and Fe^{3+} (2), which in turn results in the formation of Fe^{2+} and HO^\cdot under UV radiation (3).

The efficiency of the photo-Fenton process in the removal of the target pollutants in aqueous matrices depends on the emission spectrum of the light source, the concentration and absorbance of the photoactive species, the characteristics of the aqueous matrix in terms of oxidant demand, as well as the occurrence and concentration of other light-absorbing species, which finally result in the so-called inner filter effect.^{12–14} It is noteworthy that Fe(III) complexes are characterized by higher absorbance and quantum yield than dissolved Fe(III) , and therefore may be more important in photo-Fenton systems.¹²

As the photo-Fenton process is typically effective under acidic pH (<3) conditions, it is not an attractive option for water and urban wastewater treatment because they are characterized by neutral pH. Therefore, the target aqueous matrix should be first acidified and subsequently neutralized before effluent (re)use or disposal, leading to sludge formation and increased treatment costs. Different approaches have been investigated to overcome these limitations, including (i) process operation at mild conditions (low reagent concentrations, particularly of the metal to minimize its precipitation at pH >3);¹⁵ (ii) use of chelating agents (e.g., ethylenediamine-*N,N'*-disuccinic acid (EDDS) and nitrilotriacetic acid (NTA)) to form complexes with the metal and avoid its precipitation at neutral pH;^{16,17} (iii) heterogeneous photo-Fenton process;^{18,19} and (iv) non-iron Fenton catalysts.^{20,21} Fe(III) forms complexes with some organic compounds, typically characterized by higher molar absorption coefficients in the near-UV and visible regions than aqueous complexes. Their excitation leads to the production of Fe^{2+} and a ligand radical (4) with wavelength-dependent quantum yields.¹²

2.2 UV/ H_2O_2

Hydrogen peroxide photolysis through UV light produces the HO^\cdot radical, according to the following reaction.

Although the photolysis of H_2O_2 is characterized by a relatively high quantum yield ($\Phi \sim 1$ for HO^\cdot production, and ~ 0.5 for H_2O_2 loss), its contribution to the degradation of the target pollutants in real water matrices may be reduced due to the absorption of light by dissolved organic matter.^{12,22}

Moreover, H_2O_2 overdosing results in HO^\cdot scavenging with the formation of HO_2^\cdot (6).²³

Despite these limitations, it is possibly the only HP-AOP applied at full scale so far in potable water reuse,^{24,25} and is used as a benchmark in different research works for comparison with other AOPs or treatment methods.

2.3 UV/free chlorine

UV/free chlorine process (UV/FC) has been recently investigated in the degradation of a variety of pollutants in aqueous matrices.^{26,27} The formation of radicals is strongly affected by the pH of the aqueous solution because when chlorine (e.g., gas or hypochlorite) is added to water, hypochlorous acid (HOCl) is almost instantaneously formed and, being a weak acid, it dissociates to form hydrogen and hypochlorite ion (OCl^-). When FC ($\text{HOCl} + \text{OCl}^-$) aqueous solution is irradiated by UV light, HO^\cdot and chlorine radicals are produced according to the following reactions.^{28–30}

This process is arousing growing interest as a possible alternative to the UV/ H_2O_2 process²⁵ or as a solution to limit the formation of chlorination byproducts.³¹

2.4 UV/peracetic acid

The formation of chlorination byproducts and chlorine toxicity have increased the interest toward the use of less toxic chemicals in wastewater disinfection. Peracetic acid (PAA) has been increasingly used in WTPs as an alternative to the chlorination process.^{32–34} PAA ($\text{CH}_3\text{CO}_3\text{H}$) aqueous solutions include a mixture of acetic acid (CH_3COOH), H_2O_2 , PAA, and water, according to the following reaction.

Coupling PAA with a light source results in the formation of hydroxyl and organic radicals, according to the following reaction.³⁵

UV/PAA has been recently investigated in the removal of CECs as well as in the inactivation of bacteria in wastewater.^{36,37}

2.5 Sulfate radicals

Sulfate radical ($\text{SO}_4^{\cdot-}$)-based AOPs rely on the formation of highly reactive and short-lived $\text{SO}_4^{\cdot-}$ by cleaving the peroxide bond in the persulfate (PS) molecule *via* energy and electron transfer reactions.^{38–40} These processes have been attracting a lot of interest in the scientific community due to several potential advantages compared to HO^\cdot -based AOPs including (i) higher redox potential, (ii) higher radical formation yield, (iii) a wider variety of methods for PS activation (*e.g.*, UV radiation, heat, reduced metals, metal oxides, and some composites), (iv) less dependence on the operational parameters (in particular on pH), and (v) lower costs of storage and transportation of PS salts.⁴⁰ Similar to OH^\cdot -based AOPs, $\text{SO}_4^{\cdot-}$ -based AOPs efficiency is negatively affected by the occurrence and concentration of natural organic matter (NOM), but to a lower extent.⁴¹ However, unlike OH^\cdot -based AOPs, the efficiency of $\text{SO}_4^{\cdot-}$ AOPs is substrate specific, making these processes effective in the removal of selected target pollutants rather than in the removal of a wide variety of pollutants from complex aqueous matrices.⁴⁰

3. Challenges in the tertiary treatment of urban wastewater

3.1 Contaminants of emerging concern

CECs are synthetic or natural chemicals commonly detected in the environment that are suspected to have adverse ecological and/or human health effects.⁸ In particular, they include pharmaceuticals, personal care products, pesticides, and flame retardants, and are typically detected in freshwater and wastewater at concentrations in the range of ng L^{-1} – $\mu\text{g L}^{-1}$.⁴² Conventional urban WTPs are among the main point sources of their release into the environment because they have not been designed for their removal.⁸ Due to their poor biodegradability, CECs accumulate into the environment with possible chronic toxic and human health (through food chain) effects.² Moreover, WTPs effluents reuse is also a cause for concern because CECs can accumulate in plants irrigated with treated wastewater with possible adverse effects on human health^{43,44} and ecosystems as well as on crop performance and quality.⁴⁵ The results from the scientific literature have increased the awareness among stakeholders and policy makers about the risks related to the release of CECs into the environment;⁴⁶ despite the determination of target pollutants and their concentrations being difficult to regulate, some steps forward have been taken. For example, Switzerland implemented a new Water Protection Act in 2016, which regulates the removal of a group of CECs from urban wastewater.⁴⁷ In 2015, the European Commission established the first surface water WL under the Water

Framework Directive, a mechanism for obtaining Union-wide monitoring data on CECs and substances that may pose a significant risk to or *via* the aquatic environment.¹⁰ The list was updated in 2018 when the insecticide metaflumizone and the antibiotics amoxicillin and ciprofloxacin were added,⁴⁸ and recently, candidate substances for the 3rd WL have been proposed.⁴⁹ Moreover, the European Union recently introduced a risk assessment-based approach to identify additional water quality requirements in wastewater reuse regulation (EU 2020/741), including “(d) pharmaceuticals; (e) other substances of emerging concern; and (f) anti-microbial resistance”, which are necessary to ensure the sufficient protection of the environment and of human and animal health in wastewater reuse practices.¹¹

Ozonation and activated carbon adsorption (AC) are considered among the best available technologies (BATs) to remove CECs from secondary-treated urban wastewater, and they have been implemented at full scale in different countries, including the USA,⁵⁰ Italy,⁵¹ Switzerland, and Germany.⁵² Unfortunately, ozonation results in the formation of toxic oxidation/disinfection byproducts, and AC treatment is not effective in the inactivation of bacteria. Therefore, alternative options, such as HP-AOPs, have been successfully investigated as tertiary treatment methods for urban wastewater.⁶

3.2 Antibiotic resistance

The overuse and misuse of antibiotics promote the spread of AR in clinical settings and the environment through mobile genetic elements, including ARB and ARGs.^{53,54} WTPs are among the main hotspots for the dissemination of AR into the environment.⁴ Biological secondary treatment promotes bacterial growth under selective pressures of antibiotics, heavy metals, and other pollutants that may act as co-selectors.^{55,56} Besides vertical gene transfer (VGT) from parent to offspring, AR spread can take place through different horizontal gene transfer (HGT) mechanisms, including conjugation, transformation, and transduction (Fig. 1).⁵⁷

Recently, another mechanism named vesiduction, mediated by membrane vesicles, has been proposed as an additional pathway for AR as it plays an essential role in the HGT of ARGs, especially at the bacterial biofilm of water environments.⁵⁸ WTPs are designed to meet the limits set by national regulations for effluent disposal or reuse; therefore, no treatment unit in the WTP is designed to minimize the release of AR determinants (antibiotics, ARB, and ARGs), with the result that they are continuously released into the environment.⁴ Even the currently applied disinfection methods may not be effective in controlling AR spread,^{59,60} and the presently used methods for monitoring the process efficiency do not allow to characterize such a risk.⁶¹ In particular conditions, the disinfection process may even increase AR transfer. Chlorination was found to promote the exchange of ARGs across bacterial genera by natural

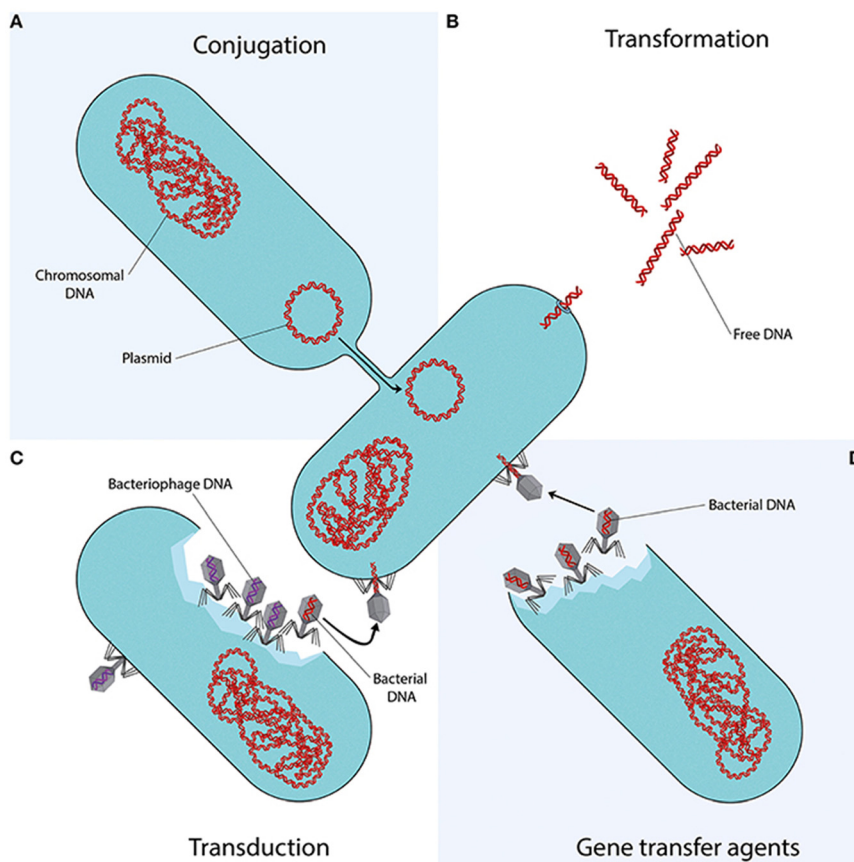

Fig. 1 Mechanisms of horizontal gene transfer. Reprinted.⁵⁷

transformation.⁶² In particular, the authors observed that chlorine-tolerant injured bacteria resulted in higher plasmid transformation frequency than untreated bacteria.

3.3 Toxicity

Chemicals typically used in wastewater disinfection can result in possible adverse effects on the receiving ecosystem. Chlorination, the most widely used disinfectant in wastewater treatment, resulted in cytotoxicity in Chinese hamster ovary cells in partially treated agricultural wastewater effluents collected from two vegetable farms.⁶³ In particular, a higher applied cumulative disinfectant concentration over time (C_t) (6.8 times higher) increased the toxicity by 1.27-fold as compared to the lower C_t value ($P < 0.05$). When chlorination was compared to the UV/H₂O₂ process in surface water disinfection in terms of pathogen inactivation and cytotoxicity potential (by means of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium colorimetric test on a human-derived cell line), 120 min treatment was necessary to reduce the cytotoxicity of UV/H₂O₂ at the control level, while cytotoxicity was always higher than the control test for the chlorination process even after an unrealistic treatment time (420 min).⁶⁴ Although ozonation was found to be less cytotoxic than chlorination in agricultural wastewater,⁶³ phyto- and eco-toxicity were observed to

increase in ozonated urban wastewater.⁶⁵ In Germany, the chemical disinfection of wastewater was stopped in the 1990s because of the toxic impact of chemicals on the aquatic flora.⁶⁶ Due to the toxic effects of chlorine and ozone on disinfected wastewater, in the recent years, alternative disinfection processes have been implemented in full-scale WTPs, including UV-C radiation and PAA. In particular, in Italy, PAA has been implemented in several WTPs to replace the chlorination process^{34,67} because WTPs effluents disinfected with PAA result in limited toxic, mutagenic, and genotoxic effects on different aquatic organisms compared to the chlorination process.⁶⁸ Although they do not result in the formation of known/regulated disinfection byproducts (DBPs), AOPs may promote the formation of oxidation intermediates more toxic than the parent compounds.^{69,70}

3.4 Disinfection and disinfection byproducts

Typically, the last step in the urban wastewater treatment train is disinfection, which aims to minimize the release of pathogens into the environment. Urban wastewater disinfection is performed through chemical (*e.g.*, chlorine gas or hypochlorites, ozone, and PAA) or physical (UV-C radiation) agents. Chemical disinfectants, such as chlorine, inactivate bacteria primarily by damaging the outer cell membrane and subsequently the cytoplasmic components,

but they are not effective against all bacteria which, if only damaged, can regrow.⁷¹ Moreover, most common chemical disinfectants result in the formation of toxic DBPs, such as trihalomethanes (THMs), haloacetic acids (for chlorination), bromates, and nitrosodimethylamine (for ozonation).^{72,73} Resistant pathogens and/or stringent limits (such as those for wastewater reuse) ask for increased chemical disinfectant doses, consequently resulting in higher concentrations of DBPs. UV-C disinfection directly targets intracellular DNA which, under favorable post-treatment conditions, can be repaired, thus enhancing cell viability and leading to bacterial regrowth.⁷⁴ AOPs do not result in the formation of known/regulated DBPs, and the produced radicals can cause oxidative damage to bacterial cells, including lipid peroxidation and protein oxidation.⁹

3.5 Wastewater reuse (and bacterial regrowth)

Wastewater reuse, in particular for crops irrigation, is an increasingly applied practice in several countries because of the water scarcity problem (even worsened by climate changes) and increasing water demand.^{75,76} One of the main challenges in wastewater reuse is to meet the stringent limits of specific bacterial indicators. According to the recently established EU Regulation on wastewater reuse (2020/741), the limit for *E. coli* to meet for “class A” effluents is <10 CFU/100 mL.¹¹ Moreover, a preliminary validation monitoring is requested to assess whether the performance targets (log₁₀ reduction) are complied with (Table 1). The indicator microorganisms selected are *E. coli* for pathogenic bacteria, F-specific coliphages, somatic coliphages, or coliphages for pathogenic viruses, and *Clostridium perfringens* spores or spore-forming sulfate-reducing bacteria for protozoa.

Bacterial regrowth after disinfection is a serious problem in wastewater treatment and reuse for crop irrigation due to the risk to public health. Although the mechanisms of light and photodriven disinfection processes (*i.e.*, during storage before reuse) remain poorly understood, bacterial regrowth can occur through (i) reactivation from a viable but non-culturable state as environmental conditions are no longer stressful for the

bacterial community, (ii) repair of photo-induced DNA damage, and (iii) reproduction of disinfection-resistant bacteria.⁷⁴ Apparently, contrasting results are available in the scientific literature on the effect of wastewater disinfection processes, but such discrepancies depend on the different operating conditions (*e.g.*, mild *vs.* intensive disinfectant/UV light doses, reactor design, and wastewater characteristics) and analytical methods. A poor experimental design and using just cultivation methods do not allow a reliable characterization of the potential for bacterial regrowth under realistic conditions. Flow cytometry and qPCR applied on 24 h/48 h-incubated disinfected samples have been recommended as complementary methods to plate counting to learn if the changes in bacterial density take place after a sufficient post-disinfection storage time.⁶¹

3.6 Microplastics

Plastic debris and particles with characteristic size between 1 and 5 mm are commonly defined as microplastics (MPs),⁷⁷ while those smaller than 1 mm are categorized as nanoplastics (NPs).⁷⁸ Major concerns are related to their release into the environment because they can be accidentally ingested, with adverse effect on different organisms even through the food chain.⁵ When they reach the WTPs through sewage, and although WTPs are not designed to remove them, they are quite effectively removed in different treatment steps.⁷⁹ Nevertheless, the amount of MPs and NPs in the effluents of WTPs is still high, being estimated in the range of 24–209% due to the possible fragmentation of MPs in NPs during the treatment steps.⁷⁹ Although disinfection methods, including ozonation,⁸⁰ UV radiation, and chlorination,⁸¹ have been found to reduce the MPs to some extent in wastewater as well as to impact their integrity,⁷⁹ the most effective methods include separation processes, particularly membrane-based technologies.⁷ Therefore, although MPs and NPs have been introduced as challenging pollutants in wastewater treatment, their removal by HP-AOPs has not received particular attention by the scientific community so far and will not be reviewed and discussed in this paper.

Table 1 Validation monitoring of “class A” reclaimed water for agricultural irrigation (Table 4, EU regulation 2020/741)¹¹

Indicator microorganisms ^b	Performance targets for the treatment chain (log ₁₀ reduction)
<i>E. coli</i>	≥5.0
Total coliphages/F-specific coliphages/somatic coliphages/coliphages ^c	≥6.0
<i>Clostridium perfringens</i> spores/spore-forming sulfate-reducing bacteria ^d	≥4.0 (in case of <i>Clostridium perfringens</i> spores) ≥5.0 (in case of spore-forming sulfate-reducing bacteria)

^a All food crops consumed raw, where the edible part is in direct contact with reclaimed water and root crops consumed raw. All irrigation methods. ^b The reference pathogens *Campylobacter*, rotavirus, and *Cryptosporidium* may also be used for validation monitoring purposes instead of the proposed indicator microorganisms. The following log₁₀ reduction performance targets shall then apply: *Campylobacter* (≥5.0), rotavirus (≥6.0), and *Cryptosporidium* (≥5.0). ^c Total coliphages is selected as the most appropriate viral indicator. However, if the analysis of total coliphages is not feasible, at least one of them (F-specific or somatic coliphages) shall be analyzed. ^d *Clostridium perfringens* spores is selected as the most appropriate protozoa indicator. However, spore-forming sulfate-reducing bacteria are an alternative if the concentration of *Clostridium perfringens* spores does not make it possible to validate the requested log₁₀ removal.

3.7 CECs removal, pathogens inactivation, and AR control: selection of model pollutants and validation tests under realistic conditions

3.7.1 CECs removal. HP-AOPs have been widely investigated for the removal of CECs and the inactivation of pathogens. The effect of radicals on CECs and pathogens also depends on the target pollutant/microorganism. For example, carbamazepine (CBZ) has been widely investigated as the model CEC and it is quite refractory to the oxidation/degradation by HP-AOPs compared to other model CECs,^{82–84} which make it a good indicator to compare different processes. On the other hand, diclofenac is easily degraded by HP-AOPs and although it has also been widely used as a model CEC, particularly because of its possible toxic effects, it is not a good indicator to compare different HP-AOPs because it is quite photosensitive.^{82,83} However, these examples show that the two mechanisms should be also taken into account when selecting the target CECs, namely, direct photolysis and indirect photolysis. Although the reactivity of CBZ toward hydroxyl and sulfate radicals is high and similar to that of other CECs, its degradation in urban wastewater drastically decreases.⁸⁵ This compound is less degraded by direct/indirect photolysis. Direct photolysis mechanism depends on the type and intensity of radiation, compound concentration, and characteristics of the wastewater, and indirect photolysis depends on the generation of ROS or excited triplet states from the photolysis of NOM, some inorganics, or even other pollutants occurring in the secondary effluent.^{86–88} Wastewater contains bicarbonate (HCO_3^-) and carbonate (CO_3^{2-}) ions, which can be transformed to carbonate radical anion ($\text{CO}_3^{\cdot-}$) when secondary urban wastewater is treated by AOPs to remove CECs, and play a role in their degradation.⁸⁹

CECs can also be sensitive to water temperature, which may cause the overestimation of HP-AOPs efficiency, particularly in solar-driven applications. This is the case of antibiotic chloramphenicol, which has been investigated as a model CEC because of its occurrence in surface water and wastewater and its carcinogenic effects, and it was found to be degraded (25%) already at 40 °C after 180 min exposure.⁹⁰ Accordingly, the correct approach for selecting the most suitable model CEC (or mixture of CECs) for evaluating the effect of the investigated process as well as to compare different processes should take into account not only its (i) toxicity, (ii) frequency, and concentration at which it is detected in water and wastewater, (iii) its relevance for the specific case study, and (iv) final use (e.g., disposal or reuse) of the treated effluent, but also its possible refractoriness to the investigated process or its sensitivity to the corresponding control tests. Moreover, the tests should not be finalized only in deionized water solutions or simulated wastewater using non-realistic concentrations (mg L^{-1}) of the target CEC, but also in real (secondary treated) wastewater (eventually spiked with 100–200 $\mu\text{g L}^{-1}$ initial concentrations, if the analytical instrument (e.g., UPLC) and method do not allow to detect

the real concentration (ng L^{-1}) at which the target CEC occurs in the real wastewater sample). It is well known that the wastewater matrix can drastically affect AOPs efficiency due to the occurrence of organic matter and radical scavengers;⁹¹ therefore, operating the process only in deionized aqueous solutions or simulated water/wastewater may significantly overestimate the process efficiency.^{15,82}

3.7.2 Pathogen inactivation. If the scope of the investigation is to evaluate the disinfection process efficiency to make the effluent in compliance with specific regulations, the model pathogens should be selected according to the relevant regulation, taking into account the possible fate of the treated wastewater, namely, disposal into the environment or reuse. The limit for wastewater reuse is typically really stringent compared to the standard for effluent disposal into a receiving water body. For example, in Italy, 10 *E. coli*/100 mL (set by Ministry Decree 93/2006) and 5000 *E. coli*/100 mL (set by Legislative Decree 152/2006) are the limit and the guide value for the reuse and effluent disposal in surface water, respectively. However, when the scope of the study is to evaluate the effect on particular microorganisms, which are suspected to be resistant to disinfection processes and/or are not yet regulated, other microorganisms can be selected accordingly. In order to achieve reliable results, disinfection tests on indigenous microorganisms in real wastewater matrix should also be performed to validate the results observed under laboratory-controlled conditions using lab growth microorganisms in saline solutions. This approach is strongly recommended as the optimum conditions have been identified because indigenous pathogens can be more resistant to disinfection process than their respective lab-grown counterparts.⁹²

3.7.3 AR control. Unlike CECs and pathogens, inconsistent and incomplete information/data are available on the possible control of AR spread by AOPs. Such inconsistency in the results available in the scientific literature and, above all, in the conclusions withdrawn by the respective research groups, also depends on the fact that no accepted/shared indicators are available, and when reference is made to some indicators (for example, the abundance and type of ARB and ARGs), the available data are not yet sufficient to identify unique and shared threshold values, and it is difficult to predict if it will ever be possible to do it.⁶¹ However, some recommendations on possible indicators/model pollutants can be provided according to the mechanisms of AR transfer explained in paragraph 3.2. The conjugation mechanism suggests that the abundance of bacterial cells can be an indicator of the potential for AR transfer; therefore, if the disinfection process drastically decreases the bacterial abundance, we can reasonably assume that the risk of AR transfer decreases accordingly. However, withdrawing the conclusion that the risk of AR has been significantly reduced because antibiotic resistant strain cells of a specific bacterial family were effectively inactivated is a conclusion not supported by sufficient evidence for different reasons: (i) the target AR bacterial family is only a small fraction of the whole

bacterial population typically occurring in wastewater; (ii) the disinfection process possibly selected for the bacterial population by increasing the relative abundance of other bacterial families more resistant than the target one and eventually with higher potential to transfer AR; (iii) the disinfection process will result in a release of ARGs and other mobile genetic elements from damaged/death bacterial cells, which may still contribute to AR transfer through transduction and natural transformation mechanisms, respectively. Therefore, the cultivation methods for the enumeration of the general bacterial population (such as total coliforms, faecal coliforms, and heterotrophic plate count), eventually coupled to flow cytometry and the quantification of relevant ARGs through quantitative real time polymerase reaction (qPCR), should be used to evaluate the relative efficiency of the investigated disinfection process compared to a consolidated one in terms of AR control.^{93,94}

4. Tertiary treatment of urban wastewater by HP-AOPs

In this paragraph, the investigation of HP-AOPs as tertiary treatment methods of urban wastewater and particularly their effect on CECs and AR is discussed. Noteworthy, while the removal of CECs by different HP-AOIPs has been widely investigated, AR has attracted the interest of the scientific community working on AOPs only recently; the need for molecular methods to analyze ARGs and better characterize the effect of treatment processes on AR make such an investigation difficult, thus explaining the lower number of manuscripts available in the scientific literature on this topic. Moreover, the higher complexity of biological/molecular

characterization compared to chemical analysis has resulted in some inconsistency among the different results published so far. Although AOPs can successfully inactivate AR in urban wastewater,^{71,95,96} this may be not sufficient to effectively reduce the risk of AR spread through HGT mechanisms due to the release of mobile genetic elements (including ARGs) from damaged/death bacterial cells and the results achieved at the lab scale under controlled conditions, far from the realistic ones, may overestimate HP-AOPs efficiency in controlling AR spread.

4.1 Photo-Fenton process

The (photo-)Fenton process is typically effective under acidic pH conditions (optimum <3); therefore, to make the process more attractive as a tertiary treatment method of urban wastewater, the use of chelating agents has been investigated to make the process effective even under neutral pH conditions.

4.1.1 Acidic vs. neutral pH conditions: are chelating agents an effective/sustainable solution for the tertiary treatment of urban wastewater? The (photo-)Fenton reaction is effective at pH <3 because as the pH increases, iron starts to precipitate drastically, thus reducing the process efficiency. Therefore, different strategies have been investigated so far, including heterogeneous photo-Fenton process,⁹⁷ mild conditions,¹⁵ and addition of chelating agents to form complexes with iron and minimize metal precipitation at neutral pH.¹⁶ The use of chelating agents in the photo-Fenton process has been widely investigated in the tertiary treatment of urban wastewater for disinfection,⁹⁸ CECs removal,⁹⁹ and AR control¹⁰⁰ because it allows to avoid the typical drawbacks of the acidic pH

Table 2 Advantages and drawbacks of chelating agents typically used in photo-Fenton treatment

Chelating agent	Advantages	Drawbacks	Ref.
EDDS	High biodegradability Wide pH range (3–9) applicability No toxicity Good efficiency in CECs removal (>60%) from secondary-treated wastewater	Lower bacterial inactivation efficiency (<i>E. coli</i> and total coliform) compared to other chelating agents, sunlight/H ₂ O ₂ , and ozonation Stability drastically affected by temperature Expensive compared to other chelating agents	14, 16, 17, 103–106
EDTA	High stability Good efficiency in CECs removal (77% of sulfamethoxazole) from secondary-treated wastewater	Poor biodegradability It can contribute to aquatic toxicity Lower <i>E. coli</i> inactivation efficiency compared to EDDS	14, 17, 107, 101
NTA	High stability during SPF High biodegradability Good efficiency in CECs removal (comparable to EDDS) from secondary-treated wastewater High inactivation of (lab) <i>E. coli</i> (6 log unit) Cheaper than EDDS	Potentially carcinogenic to humans	101–112
OA	High biodegradability Complex preparation easier than other complexing agents	Lower CECs removal efficiency compared to EDTA and NTA Large amounts required for complexation, resulting in high TOC and increased process cost	16, 101
CA	High biodegradability High removal rate of CECs (90%), comparable to EDDS, can be achieved but in low carbonates (5 mg L ⁻¹) wastewater	Higher CA dose (Fe:CA 1:4) compared to EDDS (Fe:EDDS = 1:2) is requested to achieve comparable efficiencies Low reactivity with the metal compared to other chelating agents	16, 102

process, including acidification, subsequent pH neutralization, and sludge formation, with an expectedly increased process cost. Among these, aminopolycarboxylic compounds such as ethylene diaminetetraacetic acid (EDTA), ethylenediamine-*N,N*-disuccinic acid (EDDS), and nitrilotriacetic acid (NTA), can form stable complexes with Fe^{3+} ions in a wide pH range, with optimal ratio (Fe:L) in the range of 1:1.5–1:2.0.¹⁶ Two organic acids, namely, oxalic (OA) and citric (CA) acids, have also been investigated in the removal of CECs.^{101,102} The main advantages and drawbacks of some chelating agents applied in photo-Fenton treatment are summarized in Table 2.

However, a comparison between the solar photo-Fenton (SPF) process operated under acidic and neutral pH conditions for the removal of CECs from urban wastewater led to some troubles regarding the supposedly higher operating cost of the acidic SPF.¹⁰³ Acidic pH option was found to be cheaper than the neutral pH one, mainly due to the impact of the chelating agent EDDS on the operating costs. The 15 cm depth SPF raceway pond reactor (RPR) was operated in continuous mode at 30 min HRT, 0.1 mM of iron (5.58 mg L^{-1}), 0.88 mM of H_2O_2 , and treatment capacity of $2250 \text{ L m}^{-2} \text{ d}^{-1}$ for 7.5 h operation per day, with the aim to achieve 80% CEC removal, and the total unitary costs were estimated at 0.25 € per m^3 and 0.56 € per m^3 at acidic and neutral pH, respectively. However, before making these results conclusive, it should be taken into account that the operation under acidic pH conditions increases the conductivity of the effluent due to the acidification/neutralization processes, making this option poorly attractive in case of wastewater reuse for crop irrigation. Moreover, the higher operating costs of the neutral pH condition is mainly due to the use of EDDS as a chelating agent, which account for 68% of such cost. Actually, the choice of the most appropriate chelating agent for the SPF process is dictated by the boundary conditions. The choice should fall on the chelating agent, which results in a fair compromise among the process efficiency, treatment scope, investment, and management costs. For example, EDDS has proven to be more effective than NTA in the removal of sulfamethoxazole and imidacloprid from real secondary-treated urban wastewater¹⁰⁴ but less effective than other chelating agents in the inactivation of *E. coli* and total coliforms.¹⁰⁶ Therefore, depending on the scope of the treatment (*e.g.*, CECs removal, bacteria inactivation, or both of them), the kinetics can be faster or slower, consequently affecting the reactor volume and investment costs. Moreover, EDDS is more expensive than other chelating agents, which this will affect the management costs. The investigation of new approaches as well as alternative and cheaper chelating agents is desirable and recommended to make the neutral pH process competitive in terms of operating costs. This investigation should not only evaluate the process efficiency in terms of CECs removal, but it should take into account even (i) other end points (namely, disinfection efficiency and final toxicity), (ii) chelating agent stability and biodegradability, (iii) eventually implementing LCA tools to make a final decision

on the most suitable approach for the tertiary treatment of urban wastewater by SPF. Accordingly, some recent studies have already moved in such directions. For example, López-Vinent and co-authors investigated an alternative approach by mixing different chelating agents (namely, EDDS, EDTA, and diethylenetriamine pentaacetic acid (DTPA)) to overcome the respective limitations.¹⁴ The best performance in micropollutant degradation (propranolol, acetamiprid, and sulfamethoxazole) and *E. coli* inactivation was observed for the mixing between EDDS and EDTA.

4.1.2 Effect of the photo-Fenton process on antibiotic resistance. When the efficiency of the SPF process in controlling AR spread was investigated in RPR at neutral pH ($20 \text{ mg Fe}^{2+} \text{ L}^{-1}$, $50 \text{ mg H}_2\text{O}_2 \text{ L}^{-1}$) using real urban wastewater, although *E. coli* and *Enterococcus* sp. cefotaxime resistant bacteria were effectively inactivated (detection limit (1 CFU mL^{-1}) achieved after 30–40 min, $3.2\text{--}4.7 \text{ kJ L}^{-1}$), no ARGs removal was observed.¹¹³ Similar results on ARGs were also observed when SPF ($5 \text{ mg Fe}^{2+} \text{ L}^{-1}$, $50 \text{ mg H}_2\text{O}_2 \text{ L}^{-1}$, pH 3) was operated at the pilot scale through a compound parabolic collector (CPC)-based reactor.¹⁰⁰ The aqueous matrix drastically affects the process efficiency. ARB inactivation and ARGs removal rates by photo-Fenton with EDDS as the chelating agent ($0.1:0.2:0.3 \text{ mM of Fe(III):EDDS:H}_2\text{O}_2$) decreased significantly as the complexity of the aqueous matrix increased, with removal rates in the order deionized water > synthetic wastewater > real wastewater.¹¹⁴ When the experimental apparatus/reactor and operating conditions were moved away from the real ones, different results were observed. Giannakis *et al.* observed a good efficiency of the SPF process on AR, but the operating conditions ($10 \text{ mg L}^{-1} \text{ H}_2\text{O}_2$ and $1 \text{ mg L}^{-1} \text{ Fe}^{2+}$), experimental apparatus (lab scale Suntest apparatus with a 150 W xenon lamp and an irradiation level of 750 W m^{-2}), and particularly ARGs characterization (they were not quantified through qPCR but monitored only through PCR) did not allow to quantify the actual effect of the process on the target ARGs.⁹⁶ In another work, Vilela *et al.* evaluated the effect of the SPF process (50 mg L^{-1} of H_2O_2 and 30 mg L^{-1} of Fe^{2+} , 60 min treatment, neutral pH, 400 mL glass reactor placed inside a solar simulator, 268 W m^{-2}) on the inactivation of resistance-conferring plasmids (RCPs) in synthetic secondary wastewater (SWW) using lab-grown bacteria (*E. coli* BL21 transformed with plasmids by heat-shock).¹¹⁵ The authors observed the total inactivation of RCPs by SPF within 30 min treatment in SWW. When the same research group investigated the effect of SPF (using the same experimental apparatus and H_2O_2 and Fe^{2+} doses) on the removal of several ARGs in real wastewater, the observed total removal for β -lactams and fluoroquinolones ARGs after 240 min treatment was in the range of 55–61%.¹¹⁶

4.2 UV/hydrogen peroxide

4.2.1 CECs removal. UV/ H_2O_2 is a well-established process, commonly used for organic contaminant control in drinking

water treatment plants and as a disinfection/refining step in wastewater-derived reverse osmosis permeate for groundwater recharge.²⁵ When the process was operated under sunlight, the effect in terms of CECs degradation (CBZ, flumequine (FLU), and thiabendazole (TBZ), 100 $\mu\text{g L}^{-1}$ each) in secondary-treated urban wastewater was found to be pollutant-specific and followed the order FLU > TBZ > CBZ (94%, 50%, and 12% after 90 min treatment, cumulative energy (Q_{UV}) = 4.6 kJ L^{-1}).¹¹⁷ Taking into account that a small amount of iron naturally occurs in water and wastewater, the addition of H_2O_2 in the presence of sunlight can also promote a photo-Fenton reaction, improving the radical formation and the subsequent CECs removal. When the UV-C/ H_2O_2 process was investigated, the six target CECs were removed >96% from three different secondary-treated municipal wastewaters (activated sludge (AS) (99%) > moving bed biofilm reactor (MBBR) (97%) > coagulation/flocculation (96%)) after 5 min treatment, and 99–100% removal was observed after 10 min treatment.¹¹⁸

4.2.2 Microorganisms' inactivation. H_2O_2 photolysis is particularly effective in water and wastewater disinfection. Sunlight/ H_2O_2 can result in the inactivation rates of some log units for different microorganisms in real wastewater.^{119,120} Agulló-Barceló *et al.* evaluated the effect of different solar-driven AOPs on naturally occurring *E. coli*, spores of sulphite-reducing clostridia (SRC), somatic coliphages (SPH), and F-specific RNA bacteriophages (FBPH) and sunlight/ H_2O_2 (20 mg L^{-1}) process, resulting in 5.3, 3.0, and 2.3 log inactivation for *E. coli*, FBPH, and SPH, respectively.¹¹⁹ Microorganisms inactivation by the UV-C/ H_2O_2 process in the range of 4 (2.5 min)–6 (10 min) log units in real treated municipal wastewater was observed to depend on the type of the treatment (namely, primary, AS, MBBR, and CF).¹²¹ As the inactivation mechanisms of microorganisms by sunlight/or UV-C/ H_2O_2 processes are of concern, an intracellular photo-Fenton reaction can also take place because H_2O_2 can diffuse through the cell wall and subsequently react with naturally-occurring iron inside the cell.^{122–124}

4.2.3 Effect on AR. When the effect of the UV-C/ H_2O_2 process (2.0 mM of H_2O_2 , 500 mL reactor volume, 0.45 W m^{-2} , 80 min treatment) was investigated in the inactivation of the AR *E. coli* J53 strain (3.45×10^6 CFU mL^{-1}) and its kanamycin (aphA) and tetracycline (tetA) resistant genes inoculated in sterilized real tertiary treated urban wastewater, the complete removal of both genomic and plasmid DNA was observed unlike that of the control test with the UV-C process.¹²⁵ However, in a previous work, Yoon *et al.* investigated the inactivation efficiency of plasmid-encoded ARGs (ampR and kanR), both in the extracellular form (e-ARG) and present within *E. coli* (intracellular form, i-ARG) by the UV-C/ H_2O_2 process (~ 0.3 mW cm^{-2} , 120 mL reactor volume, 10 mg L^{-1} of H_2O_2), and observed almost the same rates of e-ARG removal between UV-C control and UV-C/ H_2O_2 in real wastewater, unlike the phosphate-buffered solutions, where e-ARG removal was faster for UV-C/ H_2O_2 compared to UV-C

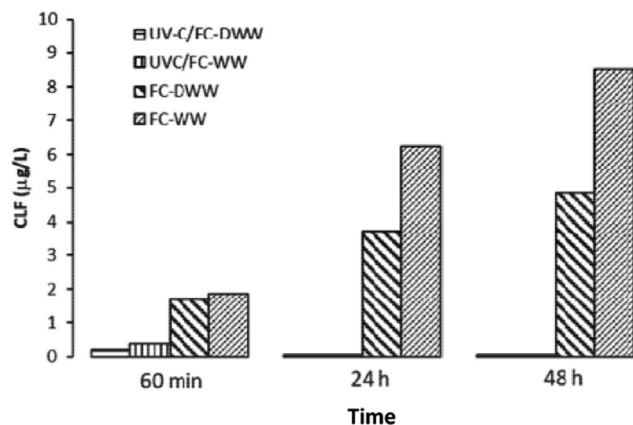

Fig. 2 Chloroform (CLF) formation after FC and UV-C/FC treatment, respectively: comparison between the end of the treatment (60 min), and 24 h and 48 h post-treatment incubation (Reprinted,³¹ Fig. 6, copyright 2020, with permission from Elsevier).

treatment.¹²⁶ Zhang *et al.* also observed the significant removal of ARGs (2.8–3.5 log of sul1, tetX, and tetG) by UV-C/ H_2O_2 (30 min treatment, UV-C fluence not provided) in secondary-treated urban wastewater, but only under conditions not feasible at full-scale (pH 3.5 and 340 mg L^{-1} of H_2O_2).¹²⁷ Moreover, when the process was investigated using a UV lamp emitting in the range of 320–450 nm under realistic conditions for wastewater treatment (pH 7.6 and 20 mg L^{-1} of H_2O_2), it was not effective in the removal of the target ARGs even after 240 min treatment.¹²⁸

4.3 UV/free chlorine

UV/free chlorine (FC) process has been increasingly investigated in the past years and it seems to be an attractive alternative option to other AOPs in the tertiary treatment of urban wastewater, such as UV/ H_2O_2 , typically applied as a final step in potable water reuse treatment train.²⁵

4.3.1 Bacterial inactivation, CECs removal, and effect on chlorination byproducts. UV-C/FC, while effectively inactivating bacteria¹²⁹ and reducing CECs, did not result in the significant formation of THMs (in particular, chloroform (CLF)) compared to the chlorination process, even after 48 h storage of treated wastewater (Fig. 2).³¹ Unlike the chlorination process, where FC reacts with organic matter to form THMs, in the UV-C/FC process, part of FC reacts with UV-C radiation to form radicals and it is no longer available to form THMs.³¹ These results are consistent with a subsequently published work where the UV-C/FC process was found to be more effective than the corresponding control tests with UV-C radiation and chlorination in the control of THMs and haloacetic acids.¹³⁰

When compared to other HP-AOPs (namely, SPF and sunlight/ H_2O_2) and conventional disinfection methods (chlorination and UV-C irradiation), the sunlight/FC process was found to be the more effective one in the inactivation of

E. coli and *Enterococcus* as well as in controlling post-treatment bacterial regrowth in inoculated roof-harvested rainwater.¹³¹

4.3.2 Effect on AR. The experimental apparatus and operating conditions strongly affect the process efficiency in terms of ARGs inactivation, and completely different results have been observed in the scientific literature, from high removal to enrichment of the target ARGs after disinfection treatment. The UV-C/FC process was more effective than UV-C and chlorination as a standalone process in the removal of *tetM* and *blaTem* genes from aqueous solutions.¹³² More specifically, the UV-C/FC process (9.03 mW cm⁻²) reduced the *tetM* and *blaTem* genes by 0.98–3.20 log and 1.28–3.36 log, respectively, as the chlorine dose was increased from 0.5 to 20.0 mg L⁻¹. However, when more realistic conditions were investigated (real secondary-treated wastewater and 0.91 mW cm⁻² UV-C dose), the target ARGs (belonging to phenicol, tetracycline, macrolide, fluoroquinolone, oxazolidinone, and penam classes of antibiotics) were found to be enriched by all the three disinfection treatments (UV-C, chlorination, and UV-C/FC), the most prominent increase being observed for UV-C/FC.¹³⁰ These results are consistent with those observed by Ping *et al.*¹³³ that compared the effect of HP-AOPs (including UV-C/FC process) with conventional disinfection processes (namely, UV-C, chlorination, and PAA) in the simultaneous removal of antibiotics and ARGs in real secondary-treated wastewater. Low (18 mJ cm⁻²) and high (108 mJ cm⁻²) UV doses (1 min and 6 min irradiation times) and low NaClO concentration (3.92 mg L⁻¹) were investigated, and β -lactam (-35.9%) and macrolides (-12.0%) ARGs remarkably increased after UV-C/FC treatment.

4.4 UV/PAA

The UV/PAA process has been poorly investigated as a tertiary treatment of urban wastewater compared to other HP-AOPs. Previous works have been mainly focused on bacterial inactivation^{34,36,134,135} and, only recently, its effect on CECs and AR has been addressed.^{37,82,133,136}

4.4.1 Effect on CECs. Rizzo *et al.* investigated the effect of the light source (sunlight Vs UV-C), water matrix (groundwater Vs wastewater), and PAA initial concentration on CECs.⁸² All the three variables investigated significantly affected process efficiency. While the results in terms of CECs degradation by sunlight/PAA are consistent with other solar-driven AOPs, CBZ removal by UV-C/PAA (22% within 180 min, 1 mg L⁻¹ of PAA, CBZ 100 μ g L⁻¹) was not in agreement with the results observed by Cai *et al.* (90% within 30 min, 1 mg L⁻¹ of PAA, CBZ initial concentration 1 μ M);³⁷ however, even these differences can be explained by the different experimental set-up, reactor design, and operating conditions. In order to evaluate the applicability of the UV/PAA process as a tertiary treatment step of urban wastewater, a comparison with other processes is necessary. According to previous works available in scientific literature, the UV/PAA process is less effective than the UV/H₂O₂ process in the

removal of CECs from both deionized aqueous solutions¹³⁶ and real wastewater.⁹⁰ Moreover, it is worthy to note that the presence of H₂O₂ in the commercially-available PAA solutions can significantly affect the removal efficiency of the target pollutants by the UV/PAA process. When H₂O₂ was quenched, the half-life time of chloramphenicol in real wastewater increased from 20 min of the UV/PAA process including H₂O₂ in the PAA solution to 99 min of UV/PAA without H₂O₂ in the PAA solution.⁹⁰ Finally, when considering the possible application of the UV/PAA process, the scavenging effect of PAA on hydroxyl radicals at high PAA concentration^{37,136} should also be taken into account.

4.4.2 Effect on AR. Rizzo *et al.* also investigated the effect of photodriven-PAA advanced oxidation process on ARB.⁸² However, the results in terms of ARB inactivation were not so consistent with the previous work, possibly due to the differences in the terms of water matrix, *E. coli* population (total vs. AR *E. coli*), and initial bacterial density.³⁴ The effect on the ARGs of the UV-C/PAA process (4 mg L⁻¹ of PAA, 18 mJ cm⁻² (low) or 108 mJ cm⁻² (high), 1 and 6 min irradiation times) in real secondary-treated urban wastewater has also been recently investigated.¹³³ The results showed that the UV-C/PAA treatment with a high UV dosage was effective to some extent in the removal of almost all the target ARGs (from 3.2% to 38.9%), while it stimulated a slight increase in *sul2* and *tetC* ARGs.

4.5 Sulphate radicals

Sulphate radicals-based HP-AOPs have only been recently investigated as the tertiary treatment of urban wastewater, and less scientific literature is available.

4.5.1 Effect on CECs. UV/PS (S₂O₈²⁻) was compared to UV/H₂O₂ and UV/FC for the degradation of six representative trace organic contaminants under conditions relevant for potable water reuse, and UV/S₂O₈²⁻ was found to be the most efficient treatment.¹³⁷ Among the three HP-AOPs, the treatment efficiency of UV/S₂O₈²⁻ was found to be more sensitive to pH, chloride, and inorganic carbon. The UV-vis/PS/Fe(II) process using solar irradiation was found to be more effective than PS/Fe(II) and UV-vis/PS processes in the removal of CBZ from both deionized water and secondary-treated urban wastewater.¹³⁸ UV-C/peroxymonosulfate (PMS) and UV-C/PMS/Fe(II) were also investigated at full scale at low dosages (0.05–0.5 mM) and short UV-C contact time (4–18 s) for the removal of antibiotics and ARGs from wastewater effluents at the Estiviel WTP (Toledo, Spain).¹³⁹ In particular, PMS (0.5 mM) combined with UV-C (7 s contact time) was the most efficient process in terms of antibiotics removal compared to other processes (including UV-C/H₂O₂).

4.5.2 Effect on bacterial inactivation and AR. Unlike that observed in the removal of antibiotics, UV-C alone was the most effective process, even better than UV-C/PMS and UV-C/PMS/Fe(II) in the removal of ARGs from real wastewater at full scale.¹³³ These results find confirmation in the previously mentioned work.¹²⁵ When the effect of UV-C- and UV-C-

Fig. 3 CPC-based reactor (a) and RPR plant (b).

driven HP-AOPs (using hydrogen peroxide, PS, and PMS as oxidant, respectively) were investigated in terms of inactivation of AR *E. coli* J53 strain, only a slight difference was observed compared to UV-C disinfection. However, when the effect on the genetic materials was investigated, any quantifiable genomic DNA in terms of *aphA* and *tetA* was observed, unlike the UV-C treatment alone, where genomic and plasmid DNA still persisted after treatment.

5. Sunlight vs. artificial light HP-AOPs

Photodriven AOPs can also be implemented using solar radiation as a light source, thus saving energy costs. This option may be feasible for small WTPs. For medium-large WTPs, sunlight-driven photo-Fenton and AOPs are not a feasible solution due to the high surface area necessary for the reactors. Solar-driven AOPs have been widely investigated in CPC-based reactors (Fig. 3a), but this technology is quite expensive (the unit cost being estimated as high as 400 € per m²); therefore, cheaper solutions, such as the RPR system (estimated cost 10 € per m²),¹⁴⁰ have been recently investigated for the tertiary treatment of urban wastewater by the SPF process.^{103–105} Though RPR systems can absorb

sunlight less efficiently than CPC reactors, they are characterized by a larger treated volume/surface ratio, and the liquid depth can easily be varied to eventually increase the treatment capacity (Fig. 3b). However, although the RPR solution decreases the investment cost compared to CPC, surface footprint is still a limitation. Therefore, it is of interest to learn if and to which extent UV-C-driven AOPs perform better (reduced contact time and, consequently, reduced reactor surface area) than solar-driven ones.

Recently, iminodisuccinic acid (IDS) has been investigated in water and wastewater treatment by the photo-Fenton-like process as the complexing agent of Cu²⁺ (ref. 21) and Fe³⁺.¹⁴¹ Interestingly, UV-C/H₂O₂/Cu-IDS was more effective than the

Table 3 Kinetic constant (*k*), *R*-squared (*R*²), and the half-life time (*t*_{1/2}) for phenol (50 mg L⁻¹, 0.53 mM) removal (as COD) by photo-Fenton and UV/H₂O₂: sunlight vs. UV-C, neutral (chelating agent) vs. acidic pH (data taken from,¹⁴¹ Table 1, Copyright 2021, with permission from Elsevier)

Process	Reagent s ⁻¹ (mM)	<i>R</i> ²	<i>k</i> (1/min)	<i>t</i> _{1/2} (min)
UV-C/Fe-IDS/H ₂ O ₂	0.021/5.53	0.9745	-0.0073	68
Sunlight/Fe-IDS/H ₂ O ₂	0.021/5.53	0.9891	-0.0114	44
UV-C/Fe ²⁺ /H ₂ O ₂ (pH 3)	0.021/5.53	0.9318	-0.0025	1000
Sunlight/Fe ²⁺ /H ₂ O ₂ (pH 3)	0.021/5.53	0.8726	-0.0029	500
UV-C/H ₂ O ₂	5.53	0.9498	-0.0010	172
Sunlight/H ₂ O ₂	5.53	0.9731	-0.0005	200

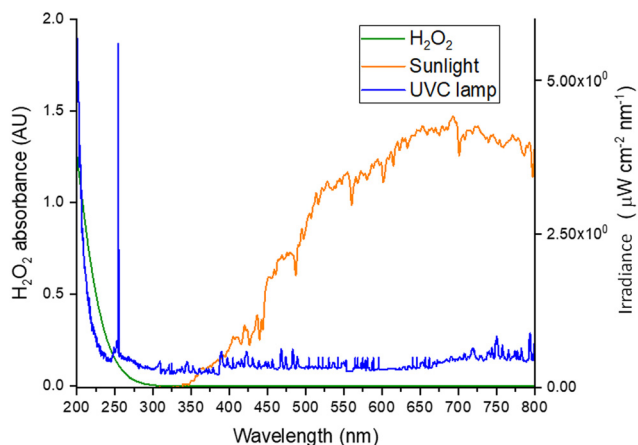

Fig. 4 The absorbance spectrum of an H₂O₂ deionized water solution (200 mg L⁻¹) and the irradiance spectra of sunlight (detected on the morning of a sunny day, July 7th 2022, at the Fisciano campus of University of Salerno (Italy) (40°76'N and 14°79'W)) and an UV-C lamp (16 W, with an emission peak at 254 nm, Sankyo Denky GT10T5L) were measured by an Ocean Optics (USA) spectrometer (model HR2000, equipped with a CC-3-UV-S cosine corrector with Spectralon as the diffusing material).

other investigated processes (UV-C/H₂O₂/Cu, UV-C/H₂O₂/Fe, and UV-C) in the inactivation of *E. coli* (complete inactivation (3.5 log units) in 10 min) at natural pH (7.8 ± 0.5) in real wastewater,²¹ while the sunlight/Fe-IDS/H₂O₂ process was found to be more effective than the UV-C-driven and pH 3 photo-Fenton processes in the degradation of phenol from aqueous solutions (Table 3).¹⁴¹

The higher efficiency of the photo-Fenton process under sunlight can be explained by the improved catalytic effect of the complex under longer wavelengths as they are able to overcome the inner filter effect.¹⁴² However, while for the other complexing agents, different works are available in the scientific literature, including the effect on CECs removal and comparisons among different chelating agents, such results are not yet available for IDS.

The sunlight/H₂O₂ process is less effective than the UV-C/H₂O₂ process because the photolytic cleavage of H₂O₂ into ·OH is mainly due to the molar absorption coefficient of H₂O₂ ($\epsilon = 18.6 \text{ l}/(\text{M cm})$) at $\lambda = 254 \text{ nm}$, and UV-C radiation is only a small fraction of the solar spectrum. Such differences can be better appreciated by comparing the absorbance spectrum of an H₂O₂ solution (200 mg L⁻¹) in deionized water, and the irradiance spectra of sunlight and a UV-C lamp, respectively (Fig. 4).

The higher performance of UV-C/H₂O₂ compared to the sunlight/H₂O₂ process was confirmed from the data in Table 2: 50 mg L⁻¹ (0.53 mM) of phenol (measured as COD) was oxidized faster by UV-C/H₂O₂ ($k = -0.0010 \text{ 1}/\text{min}$; $t_{1/2} = 172 \text{ min}$) rather than sunlight/H₂O₂ ($k = -0.0005 \text{ 1}/\text{min}$; $t_{1/2} = 200 \text{ min}$).¹⁴¹ Despite such a limitation, the sunlight/H₂O₂ process has been successfully investigated as a disinfection process (internal photo Fenton mechanism)¹²⁴ and, to some extent, for the removal of CECs from water and wastewater.^{118,120,121}

The effect of the light source was also investigated in the photolysis of PAA as a tertiary treatment method of urban wastewater by evaluating its efficiency in terms of the inactivation of AR *E. coli* and degradation of CECs. In particular, the UV-C/PAA process was found to be effective in the degradation of chloramphenicol in deionized water (25 mg L⁻¹ initial concentration, $t_{1/2} = 44 \text{ min}$, 20 mg L⁻¹ of PAA) but not effective with the sunlight/PAA process ($t_{1/2} = 410 \text{ min}$, same chloramphenicol and PAA concentrations).⁹⁰ The UV-C/PAA process was faster ($Q_{UV} = 0.3 \text{ kJ L}^{-1}$ and 0.2 mg PAA L⁻¹ were sufficient to get the LOD) than the solar driven one ($Q_{UV} = 4.4 \text{ kJ L}^{-1}$ and 0.2 mg PAA L⁻¹) in the inactivation of AR *E. coli*.⁸² However, longer exposure time and higher PAA initial dose were necessary to effectively remove the target CECs and, even in this case, the solar-driven process efficiency was lower than the UV-C-driven process.

6. Homogeneous vs. heterogeneous photodriven AOPs

Heterogeneous photodriven AOPs (HtP-AOPs) have been also investigated as the tertiary treatment of urban wastewater at

the lab and pilot scale.^{83,143} However, their possible application to water and wastewater treatment at full scale is expected to require a longer time compared to HP-AOPs due to (i) the higher interference of real aqueous matrices, (ii) process limitations (*e.g.*, low photoconversion efficiency), and (iii) technological issues (*i.e.*, removal of the photocatalyst after treatment or its immobilization on a support, catalyst preparation method, reactor design and upscale, and energy consumption).^{6,97} Although progresses in materials science have contributed to improved photocatalytic activity, HtP-AOPs are still less effective than HP-AOPs.^{143–145} In particular, solar HtP-AOPs, namely those implementing semiconductors (such as TiO₂) as the catalyst, have found to be less effective than homogenous solar-driven AOPs because, in addition to the abovementioned limitations, TiO₂ poorly absorbs radiation in the solar spectrum. Despite the attempts to improve the process performance under solar light by expanding the absorption spectrum of the photocatalyst in the visible region through TiO₂ doping with nitrogen (N-TiO₂), the N-TiO₂/sunlight process was less effective than the other investigated processes (sunlight/H₂O₂, SPF, and SPF with EDOS) in the removal of CECs from real secondary-treated urban wastewater.¹⁴³ Even when TiO₂ was used in the suspended form for the inactivation of a multidrug resistant *E. coli* strain at the pilot-scale in a compound parabolic collector reactor, sunlight/TiO₂ (50 mg L⁻¹) was found to be less effective (longer irradiation time requested for 5 log units inactivation) than SPF (Fe²⁺ = 0.090 mM (5.02 mg L⁻¹), H₂O₂ = 0.294 mM, pH 4) and sunlight/H₂O₂ (0.588 mM) processes.¹²⁰ However, SPF was found to be less effective than solar TiO₂-based HtP-AOPs in the degradation of three CECs, but in this case, the experimental conditions were not optimized and SPF was operated at pH 5.5.⁸³ Under these operating conditions, SPF also resulted in a higher environmental impact, evaluated through life cycle assessment (LCA) tool, when compared to other solar-driven AOPs, including heterogeneous ones, for the removal of three CECs (CBZ, diclofenac, and sulfamethoxazole) from a secondary-treated wastewater.¹⁴⁶ Accordingly, although SPF, either with EDOS or at acidic pH, can be more effective than HtP-AOPs, it may result in a higher environmental impact; therefore, a comparison with the support of LCA is desirable to identify the most appropriate and sustainable solution for full-scale application.

7. HP-AOPs vs. conventional tertiary treatment methods

7.1 HP-AOPs vs. ozonation

When evaluating the possible implementation of HP-AOPs at full scale as a tertiary treatment method of urban wastewater, a comparison with the best available technologies, such as ozonation, is necessary.⁵² Though ozonation results in some concerns due to the formation of toxic byproducts (such as bromate, nitrosamines, formaldehyde, and acetaldehyde) and mutagenic activity,¹⁴⁷ it is applied in central Europe countries

(particularly in Switzerland and Germany) to remove CECs from urban wastewater.⁶ Therefore, to reduce toxic and mutagenic effects, a post-treatment with biological filtration or activated carbon (BAC) adsorption is applied,¹⁴⁸ thus increasing the capital and management costs. The combination of ozonation with BAC allowed to achieve more than 90% removal for a wide range of CECs as well as a reduction of 70% of non-specific toxicity and more than 95% estrogenicity in full-scale wastewater reclamation plants located in Australia.¹⁴⁸ The effect of BAC on AR control and pathogens as ozonation post-treatment was also investigated but did not significantly improve the ARGs (*int1* and *sul1*) and pathogens (but for *C. perfringens* and somatic coliphages) compared to the ozonation process alone.¹⁴⁹

Solar-driven homogenous AOPs seem to be an attractive option alternative to ozonation for the tertiary treatment of urban wastewater in small WTPs. SPF with EDDS has been compared to the ozonation process in the inactivation of pathogens,¹⁰⁴ CECs removal, and effect on the final toxicity.¹⁰⁵ Sunlight/ H_2O_2 and SPF with EDDS were operated at near neutral pH in RPRs and compared to the ozonation process at the pilot scale in the inactivation of three pathogens (namely, *E. coli*, *Salmonella* spp., and *Enterococcus* spp.) naturally occurring in secondary-treated urban wastewater.¹⁰⁴ The inactivation rates were found to be in the following order of ozonation ($83 \text{ mg O}_3 \text{ L}^{-1} \text{ h}^{-1}$) > sunlight/ H_2O_2 (50 mg L^{-1}) > SPF (1 : 1 molar ratio, 0.1 mM of Fe (5.58 mg L^{-1}) and 50 mg L^{-1} of H_2O_2) for all the target pathogens. SPF with EDDS was also compared to ozonation (i) in the degradation of selected CECs (namely, caffeine, CBZ, diclofenac, sulfamethoxazole, and trimethoprim) at the initial concentration of $100 \mu\text{g L}^{-1}$ each and (ii) in terms of the effluent toxicity.¹⁰⁵ Ozonation was faster than SPF to achieve 80% degradation of each CEC within the early 15 min ($18.0 \text{ mg O}_3 \text{ L}^{-1}$ consumed), but while the acute toxicity evaluated by AS did not show any toxic effect, highest acute toxicity to *D. magna* was observed in ozonated wastewater samples. Moreover, significant chronic toxicity was observed for almost all the analyzed samples though the processes successfully removed (80%) the target CECs; this result can be explained by the formation of oxidation intermediates more toxic than the parent compounds.⁶⁹ SPF and sunlight/ H_2O_2 process efficiency are drastically affected by radical scavengers such as carbonates; therefore, wastewater characterized by high carbonate concentrations ($>70 \text{ mg L}^{-1}$) would need pretreatment to decrease their concentration, thus increasing the treatment cost.

Ozonation was also compared to different HP-AOPs (namely, UV/ H_2O_2 , UV/ Cl_2 , O_3 /UV, H_2O_2 / O_3 /UV, and Cl_2 / O_3 /UV) operated at the pilot-scale as a tertiary treatment method of municipal wastewater in terms of energy efficiency, CECs (namely, CBZ, fluoxetine, gemfibrozil, primidone, sulfamethoxazole, and trimethoprim) removal, DBPs formation, and pathogens inactivation.¹⁵⁰ Different ozone doses (1.5 – 9 mg L^{-1}) and UV fluences (191 – 981 mJ cm^{-2}) were investigated. Ozonation was the most energy-efficient process

in terms of electrical energy per order (EEO) parameter for CECs oxidation (with UV/ H_2O_2 and UV/ Cl_2 being the highest energy demanding processes). Among the ozone-based AOPs, only H_2O_2 / O_3 /UV did not form the ozonation byproduct bromate. Ozonation (at 1.5 – 6 mg L^{-1} doses) was the least effective process to inactivate somatic coliphages, total coliform, *E. coli*, and enterococci, while HP-AOPs were the most effective ones, resulting in the complete inactivation of selected microorganisms (1.5 mg L^{-1} ozone dose and 191 – 465 mJ cm^{-2} UV fluence).

The abovementioned results show that ozonation is an effective option for the tertiary treatment of urban wastewater, but possible additional costs for a post-treatment unit to reduce effluent toxicity and ozonation byproducts as well as to improve pathogen inactivation should be evaluated before making the final decision.

7.2 HP-AOPs vs. chlorination

Chlorination is among the most-used wastewater disinfection processes at full scale. However, the concern for the formation of toxic byproducts has promoted the use of alternative disinfection processes, such PAA and UV

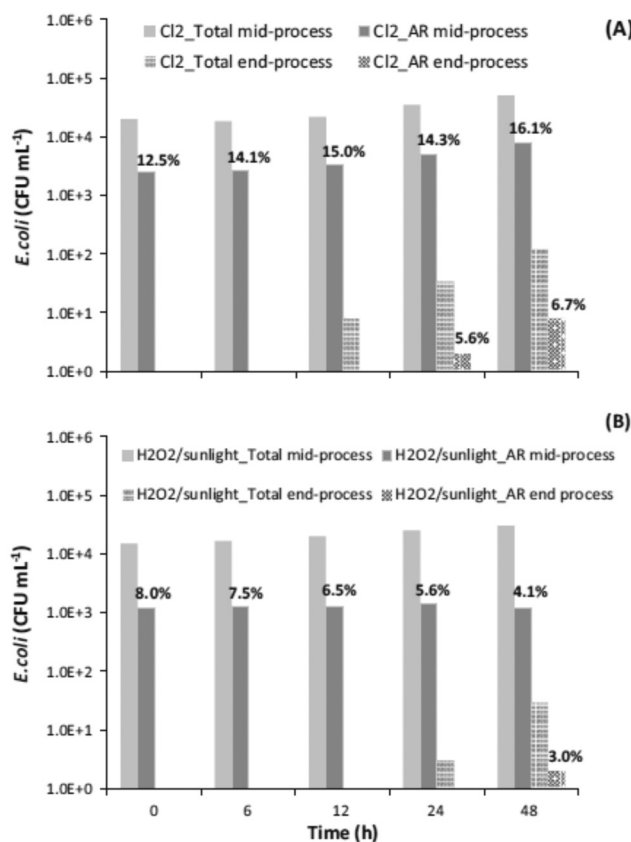

Fig. 5 Regrowth of total and MDR *E. coli* after (A) chlorination (1 mg L^{-1}) (initial total *E. coli* concentration $4.0 \times 10^4 \text{ CFU mL}^{-1}$ and initial MDR concentration $3.0 \times 10^3 \text{ CFU mL}^{-1}$) and (B) sunlight/ H_2O_2 (50 mg L^{-1}) (initial total *E. coli* concentration $2.0 \times 10^4 \text{ CFU mL}^{-1}$ and initial MDR concentration $1.0 \times 10^3 \text{ CFU mL}^{-1}$) (reprinted from ref. 71, Fig. 6, Copyright 2015, with permission from Elsevier).

radiation. HP-AOPs have also been investigated as possible alternatives to chlorination, but the higher cost compared to chlorination has not yet allowed their implementation at full scale. However, prospectively arguing, more stringent regulatory restrictions on WTPs effluents (namely, toxicity, DBPs, CECs removal, and AR control) may speed-up the implementation of HP-AOPs. In addition to the fact that they do not form regulated DBPs, other advantages have been observed. Although chlorination has resulted in faster inactivation kinetics of an indigenous multidrug resistant (MDR) *E. coli* strain in secondary-treated real urban wastewater compared to the sunlight/H₂O₂ process, it did not effectively inactivate bacterial cells that could regrow faster in post-treatment 48 h regrowth tests (Fig. 5).⁷¹

The differences observed in the two investigated processes with regard to post-treatment regrowth can be ascribed to the different inactivation mechanisms of the disinfection processes. Xu *et al.* investigated the action of the chlorination process on *E. coli* and observed that membrane permeability damage, even at low doses of chlorine (<5 mg L⁻¹), lead to the leakage of cellular adenosine triphosphate (ATP),¹⁵¹ while the effect on DNA (slight lesion) was observed only at high chlorine doses (>5 mg L⁻¹). Moreover, 5 mg L⁻¹ chlorine with 30 min contact time inhibited DNA damage repair function.

Unlike chlorination mechanisms, in light-assisted H₂O₂ disinfection, different works available in the scientific literature agree in identifying the light-enhanced internal photo-Fenton reaction as the inactivation mechanism.¹²⁴ The prevailing inactivation mechanisms involve the following processes: i) light damages the DNA and enzymes responsible for its repair (direct action); ii) light disrupts ROS-scavenging enzymes in the cells (indirect action); (iii) H₂O₂ penetrates the cell; iv) iron into the cytoplasm reacts with H₂O₂ to start a (photo)Fenton reaction with light-reducing ferric to ferrous iron; (v) and the added H₂O₂ damages the cell membrane.

8. Comparison among the processes under realistic conditions and different end-points

In order to speed up the full-scale application of HP-AOPs, it is not sufficient to compare them with other processes and consolidated technologies, but it is more important to investigate the realistic conditions (namely, real wastewater, indigenous bacteria, and environmentally-relevant CECs concentrations) using different end-points (namely, CECs removal, pathogens inactivation, effluent toxicity, and DBPs formation (when relevant)) simultaneously.⁵² Ahmed *et al.* investigated the simultaneous removal of CECs, ARB, and ARGs by photo-Fenton at neutral pH (using EDDS as the chelating agent, 0.1:0.2:0.3 mM of Fe(III):EDDS:H₂O₂) and demonstrated that the respective concentrations can be decreased to the limit of detection within 10, 30, and 15 min, respectively, in ultrapure water.¹¹⁴ But when the process was investigated in real wastewater, the detection limit was not

achieved for ARB inactivation, even after 60 min treatment. In another work, SPF resulted in poor CECs removal when compared to other solar-driven AOPs in the simultaneous removal of CECs and biological contaminants (also including ARB and ARGs) from secondary-treated urban wastewater.⁸³ This only apparent contrasting results compared to other evidences about SPF efficiency available in scientific literature can be explained by the experimental conditions, the process being operated without the addition of a chelating agent nor acidifying the solution to a pH value lower than 3, but adjusting the pH to a circumneutral value (5.5), which possibly resulted in iron precipitation, making the process less effective.

Sgroi *et al.* compared ozone-based and photodriven AOPs at the pilot scale as tertiary treatment methods of urban wastewater, using different end points (namely, CECs removal, energy efficiency, disinfection byproducts formation, and pathogen inactivation).¹⁵⁰ While ozonation resulted in the most energy-efficient technology for the removal of the target CECs, the high ozone doses needed lead to the high formation of DBPs (namely, bromate and NDMA). In particular, the significant concentration of bromate (roughly 10 µg L⁻¹, the limit set for drinking water in several countries) was detected for an ozone dose as high as 9 mg L⁻¹, while a concentration lower than 10 ng L⁻¹ NDMA (the notification value set by the California Department of Public Health (CDPH) in drinking water and in wastewater treated for potable reuse) was detected for all the ozone-based investigated processes. On the contrary, when ozone was combined with UV technology, the energy costs were significantly reduced compared to the UV/H₂O₂ and UV/Cl₂ processes. The authors concluded that, considering all the end points, the UV/H₂O₂/O₃ technology may represent a very promising option for the tertiary treatment of urban wastewater.

The limiting factor in the tertiary treatment method and consequently the operating conditions (namely, reagent doses and treatment time) depend on the secondary treatment (*e.g.*, AS, MBR, and MBBR), the end-points, the scenario (*e.g.*, effluent disposal *vs.* reuse), and regulation. Giannakis *et al.* investigated the effect of 5 photodriven (3 AOPs) processes on 3 different secondary treatment systems (namely, AS, MBBR, and CF) for the simultaneous inactivation of microorganisms, regrowth inhibition, and CECs removal.¹²¹ Using 3-log inactivation for microorganisms (analyzed through a non-selective agar, allowing the enumeration of different bacteria) and 80% removal of six CECs (according to Swiss legislation limits for micropollutants) as minimum thresholds, the best strategies in terms of the limiting factor (bacteria inactivation (and regrowth inhibition) *vs.* CECs removal) and treatment time could be defined for UV/H₂O₂ and photo-Fenton processes, respectively.

Table 4 summarizes the possible advantages, drawbacks, and recommendations for the application of HP-AOPs in the tertiary treatment of urban wastewater, according to the scientific literature reviewed in this manuscript.

Table 4 Possible advantages, drawbacks, and recommendations for the application of HP-AOPs in the tertiary treatment of urban wastewater

Advanced treatment	Advantages	Drawbacks	Recommendations
UV/H ₂ O ₂	<ul style="list-style-type: none"> Moderate-good CECs removal at lab/pilot scale Full scale evidence of high antibiotics removal Effective as a disinfection process Sunlight/H₂O₂ can be more effective than SPF in the inactivation of microorganisms 	<ul style="list-style-type: none"> Limited efficiency and large surface area required when solar radiation is used as the light source Possible formation of toxic oxidation intermediates Higher energy demand compared to ozonation 	<ul style="list-style-type: none"> Toxicity should be monitored
Photo-Fenton	<ul style="list-style-type: none"> SPF highly effective in CECs removal using chelating agents Quite effective as a disinfection process as well 	<ul style="list-style-type: none"> Possible formation of toxic oxidation intermediates To operate the process at neutral pH, the addition of chelating agents is necessary (increased operating costs) Large surface area required for the solar-driven process 	<ul style="list-style-type: none"> Toxicity should be monitored
UV/FC	<ul style="list-style-type: none"> SPF highly effective in ARGs removal at the lab scale under controlled conditions High CECs removal Reduced formation of chlorination byproducts compared to chlorination process Lower cost of sodium hypochlorite compared to hydrogen peroxide Sunlight/chlorine more effective than other solar-driven AOPs and UV-C in the inactivation of <i>E. coli</i> and <i>Enterococcus</i> 	<ul style="list-style-type: none"> Formation of chlorination byproducts Compliance of residual chlorine with limit for effluent disposal or reuse Higher energy demand compared to ozonation 	<ul style="list-style-type: none"> Chlorination byproducts and toxicity should be monitored
UV/PAA	<ul style="list-style-type: none"> Moderate-good CEC removal at lab/pilot scale under UV-C radiation Effective as a disinfection process 	<ul style="list-style-type: none"> Less effective than UV/H₂O₂ in the removal of CECs High TOC and scavenging effect, if high PAA dose is necessary Possible formation of toxic oxidation intermediates 	<ul style="list-style-type: none"> Toxicity should be monitored Not recommended when high PAA doses are necessary
UV/PS and UV/PMS	<ul style="list-style-type: none"> Full scale evidence of high antibiotics removal efficiency 	<ul style="list-style-type: none"> More sensitive to water matrix (pH, chloride, and inorganic carbon) than other HP-AOPs No improvement/less effective than UV-C in the removal of ARGs in real secondary-treated wastewater 	
UV/H ₂ O ₂ /O ₃	<ul style="list-style-type: none"> High CECs removal Reduced formation of ozonation byproducts compared to ozonation process Effective as disinfection process Evidence at pilot scale of lower energy consumption compared to UV/H₂O₂ and UV/Cl₂ 	<ul style="list-style-type: none"> Possible formation of toxic oxidation intermediates and ozonation byproducts Higher energy demand compared to ozonation 	<ul style="list-style-type: none"> Ozonation byproducts toxicity should be monitored

Although the mineralization of the CECs is desirable because it would also mean that potentially toxic oxidation intermediates have been removed, it is in fact not feasible at all because it would entail high investment (higher volumes) and operating (higher dosages of reagents for longer reaction times) costs. Therefore, it is advisable to remove the CECs and, if after their removal, the toxicity is higher than the pre-treatment wastewater, the treatment time is extended until an effluent with a lower toxicity than the influent is achieved. According to the above discussion, process selection and design as well as the operating conditions should be a compromise among different end-points.

9. Conclusions

The actual and most relevant challenge in the tertiary treatment of urban wastewater is not the identification of the optimal and sustainable conditions to obtain the removal of

a particularly refractory contaminant or a resistant microorganism, but rather obtaining the simultaneous removal or minimization of multiple contaminants under conditions that are relatively (compared to other treatments) more sustainable for the environment and safer for human health. Scientists have shown, also through pilot- and full-scale tests under realistic conditions, that HP-AOPs can effectively address the challenges in the tertiary treatment of urban wastewater and that the time for their full-scale application has almost come. Although it is hard to say to which extent they can minimize the risk of toxicity related to the release of residual concentrations of CECs or the spread of AR, we can say that they are more effective than conventional disinfection processes (such as chlorination, PAA, and UV-C radiation) and competitive with ozonation. On the other hand, the lack of a specific regulation or law in most countries on the removal of CECs and on the control of AR hinders the full-scale implementation of these processes

because they are more expensive than conventional disinfection methods. It is unlikely that WTPs managers will implement more expensive processes than traditional ones even though, as highlighted in the article, they are not effective in removing CECs and controlling AR. Among the HP-AOPs reviewed in this manuscript, the UV/H₂O₂ process is already applied as a final step in potable water reuse treatment trains, but it may have higher energy demand compared to other possible solutions (such as ozonation); however, other end points should be evaluated when making the final decision, and LCA would be a useful tool to compare different solutions. SPF has been quite exhaustively investigated and can be successfully implemented at full scale in small WTPs in RPR, particularly when wastewater is characterized by a relatively low carbonate concentration (<70 mg L⁻¹). That said, these HP-AOPs may be implemented in countries, such as Switzerland and Germany, where specific regulation is in force or concern for CECs and AR pushes WTPs managers in such direction, respectively.

Regarding the other HP-AOPs reviewed in this manuscript, a few steps are left to obtain exhaustive information/data about their possible implementation at full-scale as a tertiary treatment method of urban wastewater. To fill this gap, some advices for further investigation may be useful. In particular, the following 10 recommendations should be considered when designing the experimental plan to investigate an HP-AOP as a possible solution for the tertiary treatment of urban wastewater.

1. Scale-up of the investigated system (*e.g.*, from lab to pilot);
2. Include tests on real wastewater;
3. Investigate the effect of the process on relevant CECs at real (or at least realistic for secondary-treated urban wastewater) concentrations. Accordingly, the occurrence, toxicity (eventually, availability of risk threshold values for humans), photosensitivity (direct photolysis), contribution of indirect photolysis to the degradation of the target CEC in real wastewater, possible refractoriness to conventional, as well as to new tertiary treatment methods should be considered when selecting the target CECs;
4. Investigate the effect on indigenous bacteria (and microorganisms in general);
5. Investigate the effect on antibiotic resistant determinants taking the possible AR transfer mechanisms into account;
6. Investigate the process efficiency using different end-points simultaneously;
7. Evaluate the impact of the investigated process using proper indicators (namely, ecological, microbiological, chemical, and toxicological ones) according to the final destination of the effluent (namely, reuse or disposal into different aquatic environments or into the soil);
8. Evaluate the investigated process taking international standards for effluent disposal or reuse into account;
9. Compare the investigated process with consolidated ones;

10. Use Life Cycle Assessment tools and multi-criteria analysis to compare the investigated processes.

Acronyms

AC	Activated carbon
AR	Antibiotic resistance
ARB	Antibiotic resistant bacteria
ARGs	Antibiotic resistant genes
AS	Activated sludge
BAC	Biological activated carbon
BATs	Best available technologies
CA	Citric acid
CBZ	Carbamazepine
CECs	Contaminants of emerging concern
CLF	Chloroform
CPC	Compound parabolic collector
DBPs	Disinfection byproducts
EDDS	Ethylenediamine- <i>N,N'</i> -disuccinic acid
FC	Free chlorine
HP-AOPs	Homogeneous photodriven AOPs
MBBR	Moving bed biofilm reactor
MBR	Membrane biological reactor
MPs	Microplastics
NOM	Natural organic matter
NPs	Nanoplastics
NTA	Nitrilotriacetic acid
OA	Oxalic acid
PAA	Peracetic acid
PMS	Peroxymonosulfate
PS	Persulphate
Q _{UV}	Cumulative energy
ROS	Reactive oxygen species
RPR	Raceway pond reactor
SPF	Solar photo-Fenton
THMs	Trihalomethanes
WL	Watch list
WTP	Wastewater treatment plant
