Facile synthesis of novel 3D flower-like magnetic La@Fe/C composites from ilmenite for efficient phosphate removal from aqueous solution†

Pengchen Wang,^a Andac Armutlulu,^b Wenju Jiang,^{ac} Bo Lai^a and Ruzhen Xie ^{*,a}

In this study, a novel 3D flower-like La@Fe/C magnetic composite was successfully synthesized by carbothermal reduction of ilmenite *via* microwave radiation. The physico-chemical properties of the composite were investigated. The results showed that La@Fe/C features a 3D flower-like morphology with an S_{BET} and V_{mic} of $114 \text{ m}^2 \text{ g}^{-1}$ and $0.017 \text{ cm}^3 \text{ g}^{-1}$, respectively. Zerovalent iron and metal oxides were detected by XRD and XPS on the surface of the adsorbent, which formed as a result of carbothermal reduction of ilmenite using coconut shell-based carbon followed by the introduction of lanthanum. This resultant magnetic La@Fe/C exhibited remarkable phosphate selectivity performance even in the presence of a 50-fold excess of competing ions, which is superior to the pristine ilmenite and coconut activated carbon. Adsorption isotherms and adsorption kinetics fitted well with the Langmuir model and pseudo-second-order model, respectively. A thermodynamic study indicated that the adsorption of phosphate was spontaneous and endothermic. The adsorption–regeneration cyclic experiments of the La@Fe/C composite demonstrated a good level of recyclability. These results indicated that carbothermal reduction of ilmenite followed by the introduction of lanthanum could result in highly efficient and recoverable magnetic particles for the removal of phosphate from wastewater.

1. Introduction

Phosphates are essential nutrients for the existence of various life forms. However, excessive release of phosphate into water bodies can trigger the deterioration of water quality, collapse of the aquatic ecosystem, or even algae blooms because of eutrophication.¹ In the past few decades, various methods have been investigated for the removal of excessive phosphate from the water bodies. Adsorption has often been proposed as a promising means for phosphate removal due to its several favorable characteristics including (i) simple design, (ii) ease of operation, and (iii) high removal efficiency even at low phosphate concentration.² Various types of adsorbents such as biomass, activated carbon, metal oxide nanoparticles and hydrogel have been explored to remove phosphate from water,^{3,4} yet, enhancing the phosphate adsorption capacity and recyclability of the adsorbents remained as two important challenges to be overcome.

Among different types of oxides and hydroxides of metals tested, those of Fe, Al, La and Ca have been regarded as effective adsorbents for the removal of phosphate owing to their high phosphate binding capacity.⁵ In particular, lanthanum (La) has attracted special attention, since it is highly active in binding phosphate and forming environmentally friendly lanthanum–phosphate complex, which is highly insoluble ($\text{pK} = 26.16$).^{4,6} Therefore, lanthanum has often been preferred as a loading agent to enhance the removal of phosphate from aqueous solutions. Various La loaded porous adsorbent such as La-loaded mesoporous silica,⁷ La-loaded activated fiber⁸ and La-loaded zeolite⁹ have been proven to be favorable for improving phosphate uptake capacity. However, in spite of their promising adsorption capacity towards phosphate, their practical application is rather limited due to the difficulties encountered in separating these adsorbents from water.

Recently, coatings of magnetic iron or its (hydr)oxides on lanthanum have been offered as an effective means to enable the rapid magnetic separation of the adsorbents from aqueous solutions. Researchers have demonstrated that Fe_3O_4 -coated lanthanum ($\text{La}(\text{OH})_3/\text{Fe}_3\text{O}_4$) exhibited higher adsorption capacity toward phosphate compared to pure Fe_3O_4 .¹⁰ Among iron-based nanoparticles, zerovalent iron (nZVI) exhibited significantly higher adsorptive removal capacity towards phosphate than other adsorbents, which is caused by the synergetic effect of precipitation and chemical adsorption during the removal of phosphate.¹¹ However, nZVI has certain

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c9ra05606h

shortcomings, including ease of aggregation and oxidation, which adversely affect its adsorptive removal performance.¹² To alleviate these detrimental effects, stabilization of nZVI on carriers that are compatible with the adsorptive removal process, *i.e.*, activated carbon and activated carbon fiber, have been proposed as an effective strategy that not only reduces nZVI agglomeration, but also prevents its oxidation.¹² However, the stabilization of nZVI on carriers typically involves relatively burdensome multiple-step protocols, such as coating, reducing, washing and drying processes, which would result in a higher production cost. On the contrary, one-step pyrolysis of iron oxide with carbon possesses a greener and economically feasible way to produce affordable nZVI for environmental remediation.

This study shows first demonstration of preparing nZVI loaded particles through a one-step carbothermal reduction assisted by microwave radiation, whereby low-cost ilmenite is used as a raw material. Ilmenite is an abundant natural magnetic ore with chemical formula of FeTiO₃.¹³ After carbothermal reduction of ilmenite by coconut activated carbon (AC) *via* microwave radiation, novel magnetic nZVI-based particles with flower-like morphologies were obtained. To further improve the phosphate adsorption capacity, lanthanum was introduced into the nZVI-based particles. The physico-chemical properties of the resultant adsorbents were characterized. The influence of various parameters such as lanthanum impregnation ratio, adsorbent dosage, pH and contact time on phosphate removal were investigated in a systematic fashion and discussed in detail. Furthermore, the kinetics and thermodynamics of the adsorption process were examined. Finally, the recyclability of the adsorbents synthesized was evaluated.

2. Materials and methods

2.1 Materials

The ilmenite from Sichuan province of China was used as raw material to prepare adsorbents, which mainly consisted of (wt%): O (45.1), Fe (21.7), Ti (20.8), C (3.4), Mg (2.9), Si (2.8), Al (1.5), S (0.7), Ca (0.6), Mn (0.4), and Na (0.1). The elemental composition of the coconut activated carbon was as follows (wt%): C (85.6), H (1.5), N (0.5), O (12.4). Chemical reagents such as LaCl₃·9H₂O, KH₂PO₄, NaOH and HCl were of analytical reagent grade and used as received without further purification.

2.2 Preparation of adsorbents

For the preparation of the adsorbents, raw materials, *i.e.*, ilmenite and coconut activated carbon, were dried, grinded and sieved pass through a 200-mesh screen. 15 g of the mixed sample with a ratio of $m_{\text{ilmenite}} : m_{\text{AC}} = 4 : 1$ was then activated at 600 W for 10 min in the microwave oven under N₂ atmosphere. The resultant particles were designated as Fe/C precursor, and the magnetic particles separated from Fe/C precursor using magnet were named as magnetic precursor. For the fabrication of lanthanum-loaded Fe/C composites, 100 mL certain concentration LaCl₃ solution was added to 2 g of Fe/C precursor, and then 0.1 mol L⁻¹ NaOH solution was

introduced dropwise until the final pH reached 10.0. The final mixture was stirred at 333 K for 1 h.¹⁴ Thereafter, the slurry was dried at 378 K, followed by activation at 300 W for 2 min in the microwave oven under N₂ atmosphere. Upon cooling to room temperature, the samples were crushed and sieved through a 200-mesh screen for adsorption tests. The sample produced with impregnated lanthanum was labeled as La^x@Fe/C, where *x* refers to the impregnating concentration of La. The sample La^x@Fe/C after phosphate adsorption was named La^x@Fe/C-A.

2.3 Phosphate adsorption experiments

Phosphate solution was prepared by dissolving analytical grade anhydrous potassium dihydrogen phosphate (KH₂PO₄) in distilled water. The phosphate adsorption experiments were carried out in sealed conical flasks with 50 mL of 10 mg L⁻¹ P. The effect of lanthanum impregnation ratio, adsorbent dosage (1–8 g L⁻¹), pH (3–11) and contact time (0–180 min) was studied. After the adsorption process, the suspension was filtered through a 0.45 μm membrane, and the remaining phosphate concentration was determined according to the molybdenum blue spectrophotometric method (UV/Vis spectrophotometer at λ_{max} = 700 nm).⁸ The adsorption experiments were carried out three times, and the mean values of the tests were reported with relative standard deviation (RSD) below 0.52%.

The removal efficiency (η) of phosphate and the adsorption capacity (*q_t*) of the adsorbent were calculated according to eqn (1) and (2), respectively:

$$\eta = \frac{C_0 - C_t}{C_0} \times 100\% \quad (1)$$

$$q_t = \frac{(C_0 - C_t) \times V}{M} \quad (2)$$

where *C*₀ (mg L⁻¹) and *C_t* (mg L⁻¹) are the concentrations of the phosphate initially and at time *t* (min), respectively; η (%) is the removal efficiency of phosphate; *V* (L) is the volume of phosphate solution; and *M* (g) is the mass of the adsorbent.

The equilibrium adsorption capacity (*q_e*, mg g⁻¹) was determined as eqn (3):

$$q_e = \frac{(C_0 - C_e) \times V}{M} \quad (3)$$

where *C_e* (mg L⁻¹) is the equilibrium concentration of phosphate.

The influence of coexisting ions on the phosphate removal, such as Ca²⁺ (60–220 mg L⁻¹), Cl⁻ (50–300 mg L⁻¹), NO₃⁻ (50–300 mg L⁻¹), SO₄²⁻ (50–300 mg L⁻¹), and CO₃²⁻ (50–300 mg L⁻¹) were evaluated in batch experiments with phosphate concentration of 10 mg L⁻¹. The La@Fe/C after phosphate adsorption were calcined at 673 K, washed, and dried for further regeneration tests.

The mechanism for phosphate adsorption onto the adsorbents was studied by fitting the kinetic data with pseudo-first-order model, pseudo-second-order model and intra-particle-diffusion model (eqn (4)–(6)).^{15–17}

$$\ln(q_e - q_t) = \ln q_e - k_1 t \quad (4)$$

$$\frac{t}{q_t} = \frac{1}{k_2 q_e^2} + \frac{1}{q_e} t \quad (5)$$

$$q_t = k_{id} t^{1/2} + C \quad (6)$$

where q_e and q_t (mg g^{-1}) are the respective adsorption capacities at equilibrium and at time “ t ” (min); k_1 , k_2 and k_{id} are the rate constants of pseudo-first-order model, pseudo-second-order model and intra-particle-diffusion model, respectively, and C is a constant related to the extent of the boundary layer thickness.

Three widely used isotherms including Langmuir, Freundlich and Temkin models were applied to fit the experimental data for adsorbing phosphate onto adsorbent (eqn (7)–(9)).^{18–20}

$$\frac{C_e}{q_e} = \frac{C_e}{q_m} + \frac{1}{k_L q_m} \quad (7)$$

$$\ln q_e = \ln k_F + \frac{1}{n} \ln C_e \quad (8)$$

$$q_e = B_T \ln A_T + B_T \ln(C_e) \quad (9)$$

where q_m (mg g^{-1}) and k_L (L mg^{-1}) are Langmuir constants related to the adsorption capacity and the adsorption rate, respectively; k_F ($(\text{mg g}^{-1}) (\text{L mg}^{-1})^{-1/n}$) and n are the constants and a measure of the adsorption intensity, respectively. $B_T = RT/b$, where b (J mol^{-1}), A_T (L mg^{-1}), R ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$) and T (K) are the Temkin constant related to the heat of adsorption, equilibrium binding constant, gas constant and absolute temperature, respectively.

Thermodynamic parameters including enthalpy (ΔH^0), entropy (ΔS^0) and free energy (ΔG^0) were calculated using the eqn (10) and (11):²¹

$$\ln k_d = \frac{\Delta S^0}{R} - \frac{\Delta H^0}{RT} \quad (10)$$

$$\Delta G^0 = -RT \ln k_d \quad (11)$$

where k_d is the distribution coefficient; ΔS^0 ($\text{kJ mol}^{-1} \text{ K}^{-1}$) is the standard entropy; ΔH^0 (kJ mol^{-1}) is the standard enthalpy; R ($8.314 \text{ J mol}^{-1} \text{ K}^{-1}$) is the gas constant and T (K) is the absolute temperature.

2.4 Characterization of adsorbents

N_2 adsorption–desorption isotherm of samples was measured at 77 K using the surface area analyzer (ASAP 2460, Norcross, GA). The specific surface area (S_{BET}), total pore volume (V_{tot}), mesopore volume (V_{mes}), micropore volume (V_{mic}), and pore size distribution were obtained from the N_2 adsorption–desorption isotherms using the Brunauer–Emmett–Teller (BET) equation, N_2 adsorption amount at the maximum relative pressure, Barrett–Joyner–Halenda (BJH) method, t -plot method, and density functional theory (DFT) method, respectively.

The crystallinity and phase identification of adsorbents were determined by XRD (X-Pert PRO MPD, Panalytical, NL) with Cu

$\text{K}\alpha$ as the radiation source under 36 KV with 2θ range of 10 – 80° . The surface chemistry was determined by an X-ray photoelectron spectroscopy (XPS) (XSAM-800, KRATOS, UK) with Al (1486.6 eV) under ultra-high vacuum at 12 kV and 15 mA.

Fourier Transforms Infrared Spectroscopy (FTIR) characterization was carried out with a spectrometer (Tensor 27 spectrometer, FTIR-6700, Nicolet, USA) in the range of 4000 – 400 cm^{-1} with a resolution of 4 cm^{-1} . The Scanning Electron Microscopy (SEM) measurement was carried out using SEM (JEOL, JSM-7500 F, Japan). pH point of zero charge (pH_{PZC}) was measured by the method described by Moharami and Jalali to investigate the total surface charge of the adsorbents.²²

3. Results and discussion

3.1 Characterization of the adsorbents

3.1.1 Textural properties. The textural properties of the adsorbents synthesized are shown in Table 1, which were calculated on the basis of their N_2 adsorption–desorption isotherms. N_2 isotherms (Fig. S1 in ESI†) showed that the pristine ilmenite had no obvious porosity, while coconut AC and La@Fe/C had hierarchical pore structure with obvious hysteresis loop (Fig. S1b and d†).²³ As can be seen from Table 1, the specific surface area (S_{BET}) of pristine ilmenite, coconut AC, and Fe/C precursor were $0.3 \text{ m}^2 \text{ g}^{-1}$, $1590 \text{ m}^2 \text{ g}^{-1}$, and $270 \text{ m}^2 \text{ g}^{-1}$, respectively. After La modification, the S_{BET} of La^{0.001}@Fe/C, La^{0.005}@Fe/C, La^{0.06}@Fe/C and La^{0.12}@Fe/C were $106 \text{ m}^2 \text{ g}^{-1}$, $114 \text{ m}^2 \text{ g}^{-1}$, $115 \text{ m}^2 \text{ g}^{-1}$, and $117 \text{ m}^2 \text{ g}^{-1}$, respectively, all of which are substantially smaller than the Fe/C precursor. The reduction of the S_{BET} after La doping may possibly result from the formation of aggregated La/Fe-nanocomposites leading to an increased particle size.¹⁰ The micropore volume (V_{mic}) and mesopore volume (V_{mes}) of La@Fe/C (in range of 0.011 – $0.237 \text{ cm}^3 \text{ g}^{-1}$ and 0.041 – $0.167 \text{ cm}^3 \text{ g}^{-1}$, respectively) are much higher than that of pristine ilmenite (0.00007 and $0.00119 \text{ cm}^3 \text{ g}^{-1}$, respectively), suggesting that large amount of porosities were formed on La@Fe/C during carbothermal reduction of ilmenite.

Table 1 further compares the adsorption performance of the mentioned adsorbents with a concentration of 1 g L^{-1} tested in 10 mg L^{-1} phosphate solution. It was obvious that both AC and ilmenite exhibited relatively low phosphate adsorption capacity, with q_e value of 2.73 mg g^{-1} and 0.79 mg g^{-1} , respectively. However, upon carbothermal reduction of ilmenite, the resulting Fe/C precursor exhibited a substantially higher adsorption capacity (*i.e.*, $q_e = 5.61 \text{ mg g}^{-1}$), which could be attributed to the generation of active sites, *i.e.*, nZVI (Fe^0) and Fe_2O_3 , for phosphate removal. It can also be seen that although La^{0.12}@Fe/C has the lowest microporosity, it possesses the highest adsorption capacity toward phosphate, which is possibly linked to the higher lanthanum loading providing more active sites on La^{0.12}@Fe/C for binding phosphate. An interesting point to note is that La^{0.005}@Fe/C ($q_e = 7.20 \text{ mg g}^{-1}$) showed higher phosphate uptake capacity than La^{0.06}@Fe/C ($q_e = 6.43 \text{ mg g}^{-1}$), which might be related to the higher microporosity of La^{0.005}@Fe/C ($V_{\text{mic}} = 0.017 \text{ cm}^3 \text{ g}^{-1}$) as compared to La^{0.06}@Fe/C ($V_{\text{mic}} = 0.011 \text{ cm}^3 \text{ g}^{-1}$). Since the hydrated radius of phosphate species (*i.e.*, $\text{H}_2\text{PO}_4^{3-}$, PO_4^{3-} , and HPO_4^{2-}) is less than

^a S_{BET} , BET surface area; V_{tot} , total pore volume; V_{mes} , mesopore volume; V_{mic} , micropore volume; D_{mean} , average pore diameter; q_e , adsorption capacities toward 10 mg L^{-1} phosphate; $\text{La}^{0.005}\text{@Fe/C-A}$: $\text{La}^{0.005}\text{@Fe/C}$ after phosphate adsorption.

0.339 nm, micropore was favored for the removal of phosphate.²⁴ Although $\text{La}^{0.12}\text{@Fe/C}$ exhibited the highest phosphate removal capacity, to minimize the use of La chemicals, $\text{La}^{0.005}\text{@Fe/C}$ particles were selected for further studies.

Fig. 1 showed the SEM images for ilmenite, precursor (*i.e.*, Fe/C), and the adsorbent of interest before and after phosphate adsorption (*i.e.*, $\text{La}^{0.005}\text{@Fe/C}$ and $\text{La}^{0.005}\text{@Fe/C-A}$). It can be seen that seldom pores can be observed on the pristine ilmenite, while the Fe/C precursor exhibited a porous structure with flower-like morphology (Fig. 1d–f). Further loading of La did not destruct the 3D flower-like morphology (Fig. 1g–i). Such morphologies with submicron level pore sizes are favorable for adsorption purposes. Fig. 1g–i demonstrate that $\text{La}^{0.005}\text{@Fe/C-A}$ could maintain its 3D flower-like structure after phosphate adsorption. The nm-sized lamellar structure found on the $\text{La}^{0.005}\text{@Fe/C-A}$ can be ascribed to the formation of insoluble

lanthanum–phosphate complex and iron–phosphate complex on the surface of $\text{La}^{0.005}\text{@Fe/C}$. The porous morphology of $\text{La}^{0.005}\text{@Fe/C}$ did not undergo a significant change upon phosphate adsorption (Fig. 1e vs. Fig. 1h).

3.1.2 XRD analysis. XRD patterns of ilmenite, Fe/C precursor, magnetic precursor, $\text{La}^{0.005}\text{@Fe/C}$ and $\text{La}^{0.005}\text{@Fe/C-A}$ are shown in Fig. 2. The detected peaks on Fig. 2a at $2\theta = 23.825^\circ$, 32.588° , 35.257° , 40.323° , 48.766° , 53.136° , 61.594° , 63.269° and 70.304° for ilmenite are assigned to FeTiO_3 (JCPDS 71-1140).

New peaks appeared following the microwave radiation treatment, as shown in Fig. 2b–d, which resulted from the carbothermal reduction reactions between ilmenite and activated carbon. As can be seen in Fig. 2b–d, the new peaks at $2\theta = 23.802^\circ$, 35.305° , 44.504° , 48.532° , 53.420° , 61.694° , 63.539° , 75.037° and 76.628° , and $2\theta = 32.802^\circ$, 35.193° , 44.879° , 61.751°

Fig. 1 SEM for (a) ilmenite, (b, c) Fe/C precursor, (d–f) $\text{La}^{0.005}\text{@Fe/C}$, and (g–i) $\text{La}^{0.005}\text{@Fe/C-A}$.

and 70.236° were corresponding to TiO_2 (JCPDS 46-1237) and Fe_2O_3 (JCPDS 16-0653), respectively.

Furthermore, the characteristic diffraction peaks in Fig. 2d and e at $2\theta = 25.328^\circ$, 44.634° , 59.955° can be indexed to La_2O_3 (JCPDS 40-1281). Fe^0 was found at $2\theta = 44.669^\circ$ and 65.000° (JCPDS 16-0696) on the XRD patterns of magnetic precursor, which confirmed the formation of nZVI *via* carbothermal reduction of ilmenite. Moreover, $\text{Fe}_{12}\text{LaO}_{19}$ was also detected at $2\theta = 35.164^\circ$, 40.605° , 55.294° and 56.402° (JCPDS 13-0474), indicating that the La-Fe nanocomposites were also formed during microwave heating. These results are in line with the studies showing that TiO_2 and Fe_2O_3 can be obtained by high-temperature activation of ilmenite.²⁵ TiO_2 formed in the adsorbent did not undergo further structural changes, despite the extremely high reaction temperature.^{26,27} The diffraction peaks of Fe^0 were not obvious except for the XRD pattern of the magnetic precursor, which could originate from the small grain size and good dispersion of Fe^0 on $\text{La}^{0.005}\text{@Fe/C}$.

After adsorbing phosphate, new peaks were observed on $\text{La}^{0.005}\text{@Fe/C-A}$ (Fig. 2e). The peaks located at $2\theta = 25.281^\circ$ and 40.264° can be ascribed to FePO_4 (JCPDS 31-0647) and peaks at $2\theta = 25.281^\circ$, 48.375° , 51.909° , 53.210° and 56.027° belonged to LaPO_4 (JCPDS 04-0635). These detected peaks of FePO_4 and LaPO_4 on the surface of $\text{La}^{0.005}\text{@Fe/C-A}$ are indicative of the reactions between phosphate and metal/metal oxides during the adsorption process. Thus, the mechanism between phosphate and metal/metal oxides in $\text{La}^{0.005}\text{@Fe/C}$ during the adsorption process could be proposed as ion exchange or metal phosphate precipitation process as shown in eqn (12).

3.1.3 XPS analysis. XPS was used to analyze the elemental composition and the chemical bond state on the surface of $\text{La}^{0.005}\text{@Fe/C}$ and $\text{La}^{0.005}\text{@Fe/C-A}$. The relative content of elements in adsorbent were: C 62.39 wt%, O 23.54 wt%, Fe 8.08 wt%, La 4.87 wt%, Ti 1.12 wt%. The XPS spectra of magnetic precursor were also analyzed to clarify the status of iron in the composites. As shown in Fig. 3a, the respective binding energies of Ti $2p_{3/2}$ and Ti $2p_{1/2}$ were found to be 460.5 eV and 466.3 eV for $\text{La}^{0.005}\text{@Fe/C}$.

After phosphate adsorption, no significant change was observed in the binding energy of Ti on $\text{La}^{0.005}\text{@Fe/C-A}$. Moreover, the difference between the binding energies of Ti $2p_{3/2}$ and Ti $2p_{1/2}$ on the spectra of $\text{La}^{0.005}\text{@Fe/C}$ and $\text{La}^{0.005}\text{@Fe/C-A}$ was equal to 5.8 ± 0.1 eV, which might point to the presence of TiO_2 on $\text{La}^{0.005}\text{@Fe/C}$ and $\text{La}^{0.005}\text{@Fe/C-A}$.^{28–30} The fact that TiO_2 can still be detected in $\text{La}^{0.005}\text{@Fe/C-A}$ after phosphate adsorption indicates that TiO_2 did not react with phosphorus to form complexes.

The binding energy of Fe $2p_{3/2}$ with peaks for Fe(III), Fe(II) and Fe(0) appeared at 713.5–714.1, 711.5–712.0 and 708.2 eV, respectively, and the Fe $2p_{1/2}$ peaks for Fe(III) and Fe(II) centered at 725.8–726.0 and 717.0–717.4 eV, respectively.^{31,32} Thus, the presence of Fe^{3+} , Fe^{2+} and Fe^0 in samples confirmed that FeTiO_3 in ilmenite was reduced by C in activated carbon, and the

formation of nZVI took place under microwave radiation. Moreover, the binding energy peak of La $3d_{5/2}$ at around 838.0 eV and La $3d_{3/2}$ at 854.0 eV indicated the existence of La^{3+} in La_2O_3 ,³³ which suggests the formation of La_2O_3 *via* the calcination of LaCl_3 at 673 K. Following phosphate adsorption, slight changes were observed in the binding energies for Fe 2p and La 3d of $\text{La}^{0.005}\text{@Fe/C}$ as shown in Fig. 3b and c, which suggest that Fe and La were involved in the phosphate removal process. These results were also confirmed by the XRD analysis, whereby FePO_4 and LaPO_4 could be detected in the spectra of $\text{La}^{0.005}\text{@Fe/C-A}$ (Fig. 2e).

3.1.4 FTIR analysis. Fig. 4 showed the FTIR spectra of $\text{La}^{0.005}\text{@Fe/C}$ before and after phosphate adsorption. No obvious difference was observed between the bands of $\text{La}^{0.005}\text{@Fe/C}$ and $\text{La}^{0.005}\text{@Fe/C-A}$. Three characteristic bands at 3440 cm^{-1} , 1068 cm^{-1} and 560 cm^{-1} were found for both $\text{La}^{0.005}\text{@Fe/C}$ and $\text{La}^{0.005}\text{@Fe/C-A}$. The peak at about 3440 cm^{-1} can be assigned to the O–H stretching vibration, which was indicative of the presence of hydroxylic, carboxylic, and phenolic groups (including hydrogen bonding) in the coconut AC matrix.³⁴ The peak at 1068 cm^{-1} was assigned to the asymmetric stretch vibration of P–O, and the peak at 560 cm^{-1} was related to the vibration of O–P–O.³⁵ It is noteworthy that, the La–O coordination peak vibration was found at 484 cm^{-1} on $\text{La}^{0.005}\text{@Fe/C-A}$, which possibly happened due to the reaction between the La and the oxygen anion in the phosphate molecule.³⁶ Furthermore, the bands at 1068 cm^{-1} became stronger after adsorbing phosphate, suggesting the existence of PO_4^{3-} on $\text{La}^{0.005}\text{@Fe/C-A}$.³⁷

3.2 Batch experiments

3.2.1 Effect of adsorbent dosage. The effect of adsorbent dosage on phosphate adsorption was studied with adsorbent dosages ranging from 1 to 8 g L^{-1} in 10 mg L^{-1} phosphate solution, and the results were shown in Fig. 5. As can be seen,

Fig. 2 XRD patterns of (a) ilmenite, (b) Fe/C precursor, (c) magnetic precursor, (d) $\text{La}^{0.005}\text{@Fe/C}$, and (e) $\text{La}^{0.005}\text{@Fe/C-A}$.

Fig. 3 XPS spectra of (a) Ti 2p, (b) Fe 2p, and (c) La 3d patterns for magnetic precursor, $\text{La}^{0.005}\text{@Fe/C}$ and $\text{La}^{0.005}\text{@Fe/C-A}$.

$\text{La}^{0.005}\text{@Fe/C}$ showed substantially higher phosphate adsorption capacity, in particular at the lower range of adsorbent dosages, when compared to the coconut shell based activated carbon (AC) and ilmenite. This high phosphate adsorption capacity of $\text{La}^{0.005}\text{@Fe/C}$ can be attributed to the reaction of phosphate with lanthanum and iron located on the surface of the adsorbent, and thus, formation of insoluble phosphate complex, as per shown by the XRD, XPS and FTIR results. The removal efficiency of phosphate by $\text{La}^{0.005}\text{@Fe/C}$ increased from 72.0% to 93.3% with the increasing dosage of $\text{La}^{0.005}\text{@Fe/C}$ from 1 g L^{-1} to 8 g L^{-1} , this was because higher dosage of adsorbents enabled more active sites for phosphate removal. However, the phosphate adsorption amount decreased from 7.20 mg g^{-1} to 1.17 mg g^{-1} with the dosage increasing from 1 g L^{-1} to 8 g L^{-1} , which might possibly stem from the overlapping of available activated sites on the adsorbent. Thus, the dosage of adsorbents with 1 g L^{-1} was selected for the further phosphate removal experiments.

3.2.2 Effect of contact time. The effects of contact time on AC, ilmenite and $\text{La}^{0.005}\text{@Fe/C}$ are presented in Fig. 6. Ilmenite

and $\text{La}^{0.005}\text{@Fe/C}$ showed fast adsorption within the initial 30 min, and then the adsorption process gradually slowed down and reached equilibrium at nearly 90 min, while the equilibrium time for AC was around 120 min. This was because at initial stage, large amount of vacant adsorption sites was available on the surface and internal structure of AC, ilmenite and $\text{La}^{0.005}\text{@Fe/C}$. As the adsorption process continued, the active sites on the adsorbents gradually saturated and hardly adsorb phosphate.⁸ As shown in Table 1, AC, Fe/C precursor, and $\text{La}^{0.005}\text{@Fe/C}$ presented microporosity in the order of $\text{AC} > \text{Fe/C precursor} > \text{La}^{0.005}\text{@Fe/C}$, whereas the adsorption capacities for the removal of phosphate is in the order of $\text{La}^{0.005}\text{@Fe/C} > \text{Fe/C precursor} > \text{AC}$, which could be due to different chemical properties of these adsorbents. Upon a three-hour-long exposure, $\text{La}^{0.005}\text{@Fe/C}$ exhibited higher phosphate capacity (7.36 mg g^{-1}) when compared to AC (2.27 mg g^{-1}) and Fe/C precursor (5.71 mg g^{-1}), as shown in Fig. 6 The stronger adsorptive performance of $\text{La}^{0.005}\text{@Fe/C}$ towards phosphate can be attributable to the more active sites available on the surface of $\text{La}^{0.005}\text{@Fe/C}$, as compared to the Fe/C precursor and AC.

Fig. 4 FTIR spectra of (a) $\text{La}^{0.005}\text{@Fe/C}$ and (b) $\text{La}^{0.005}\text{@Fe/C-A}$.

Fig. 5 Influences of different adsorbent dosages on phosphate adsorption and removal efficiency of different adsorbents.

3.2.3 Effect of pH. Another important factor to be taken into consideration is the pH of the solution, which can affect both the degree of adsorbate ionization and the surface charge of the adsorbent in the solution. The influence of pH on the removal of phosphate by $\text{La}^{0.005}\text{@Fe/C}$ was investigated at different pH values ranging from 3 to 11, and the results are shown in Fig. 7. It can be seen that a pH increases from 3 to 7 yielded a higher uptake of phosphate, whereby the maximum phosphate adsorption amount was achieved at pH = 7. It was reported that within the pH range of 3–8, H_2PO_4^- is the dominant phosphate species in the solution.⁶ Since the zero point of charge (pH_{pzc}) of $\text{La}^{0.005}\text{@Fe/C}$ is 7.45, a pH value lower than 7.45 causes the surface of $\text{La}^{0.005}\text{@Fe/C}$ to become positively charged, which further favors the electrostatic interaction and ion exchange with H_2PO_4^- . As the pH value increased further from 7 to 11, the adsorption capacity decreased from 7.28 mg g^{-1} to 6.70 mg g^{-1} . This was mainly caused by the fact that alkaline pH generates repulsive electrostatic forces, weakening the active adsorption sites for ion exchange due to the high concentration of OH^- in the solution.³⁸

3.3 Adsorption mechanism

3.3.1 Adsorption kinetics. The kinetic modeling were fitted to the pseudo-first-order, pseudo-second-order model and intra-particle diffusion. Results (see Fig. 8 and Table 2) showed that the experimental kinetic data can be best described by pseudo-second-order model with R^2 for AC, precursor and $\text{La}^{0.005}\text{@Fe/C}$ were 0.9908, 0.9996 and 0.9998, respectively. The calculated q_e values ($q_{e,\text{cal}} = 2.32, 5.74, 7.44 \text{ mg g}^{-1}$ for AC, precursor and $\text{La}^{0.005}\text{@Fe/C}$, respectively) were in well agreement with the experimental values ($q_{e,\text{exp}} = 2.27, 5.71, 7.36 \text{ mg g}^{-1}$ for AC, precursor and $\text{La}^{0.005}\text{@Fe/C}$, respectively). These results confirmed that the phosphate adsorption process might be controlled by the chemisorption process.³⁹ For a better understanding of the adsorption mechanism, intra-particle-diffusion model was further applied to fit the experimental data. As can

be seen from Fig. 8, the adsorption kinetics curve of intra-particle-diffusion model can be divided into two major phases, the first phase showed a higher rate constant K_{id1} of $\text{La}^{0.005}\text{@Fe/C}$, which indicated a higher removal rate in the beginning due to the large available surface area and high amount of active sites on the external surface.¹⁷ The lower use of K_{id2} could be related to the smaller amount of adsorption sites on the adsorbent, limiting the intra particle diffusion. It is noteworthy that the plot did not pass through the origin, which suggests that intra-particle-diffusion was not the key step to control the adsorption process. Some other mechanisms such as initial external mass transfer may also be involved in the phosphate adsorption process.⁴⁰

3.3.2 Adsorption isotherms. The equilibrium data were fitted to the Langmuir, Freundlich and Temkin isotherm models (Fig. 9), and the adsorption constants were presented in Table 3. The adsorption of phosphate onto $\text{La}^{0.005}\text{@Fe/C}$ fitted best to Langmuir model ($R^2 = 0.9980$), suggesting that the adsorption of phosphate on $\text{La}^{0.005}\text{@Fe/C}$ was based on monolayer homogeneous adsorption process. It could be seen from Table 3 that the q_e of $\text{La}^{0.005}\text{@Fe/C}$ calculated from the Langmuir model increased from 32.16 mg g^{-1} at 293 K to 39.90 mg g^{-1} at 323 K, indicating that the adsorption of phosphate onto $\text{La}^{0.005}\text{@Fe/C}$ was an endothermic process.⁴¹ The value of k_L , calculated from Langmuir isotherm was 0.08–0.10, suggesting a favorable adsorption of phosphate on $\text{La}^{0.005}\text{@Fe/C}$. In addition, the value of n calculated from Freundlich model is 1.88, pointing to a chemically favorable and heterogeneous adsorption of phosphate onto $\text{La}^{0.005}\text{@Fe/C}$.⁴² The Temkin constant b was related to the heat of adsorption, and its values were positive for all temperatures ($b = 321.84 \text{ J mol}^{-1}$ at 293 K), which also confirms the fact that adsorption of phosphate onto $\text{La}^{0.005}\text{@Fe/C}$ was endothermic process.⁴³

3.3.3 Thermodynamic analysis. Thermodynamic parameters for phosphate adsorption onto $\text{La}^{0.005}\text{@Fe/C}$ were evaluated at 293 K, 303 K, 313 K and 323 K using eqn (10) and (11). The positive value of ΔH^0 (3.40 kJ mol^{-1}) indicates that phosphate

Fig. 6 Influences of contact time on the phosphate adsorption of AC, Fe/C precursor and $\text{La}^{0.005}\text{@Fe/C}$.

Fig. 7 Influences of pH on phosphate adsorption by $\text{La}^{0.005}\text{@Fe/C}$.

Fig. 8 Kinetic modeling of: (a) pseudo-first-order model, (b) pseudo-second-order model, and (c) intra-particle diffusion model for phosphate adsorption on the adsorbents.

adsorption onto $\text{La}^{0.005}\text{@Fe/C}$ is an endothermic process, while the negative values of ΔG^0 ($-2.44 \text{ kJ mol}^{-1}$, $-2.64 \text{ kJ mol}^{-1}$, $-2.84 \text{ kJ mol}^{-1}$, and $-3.04 \text{ kJ mol}^{-1}$) at temperature of 293 K, 303 K, 313 K and 323 K, respectively, indicated the phosphate adsorption occurs spontaneously.⁴⁴ The positive value ΔS^0 ($0.02 \text{ kJ mol}^{-1} \text{ K}^{-1}$) showed the affinity of $\text{La}^{0.005}\text{@Fe/C}$ for adsorbing phosphate and the increasing randomness at the solid-solution interface with some structural changes in the adsorbates and adsorbents during the adsorption process.⁴⁵

3.4 Influence of coexisting ion

The influence of coexisting ions in waste water such as NO_3^- , Cl^- , CO_3^{2-} , SO_4^{2-} and Ca^{2+} (ref. 46) on phosphate (10 mg L^{-1}) adsorption was investigated, and the results are presented in Fig. 10. It can be observed from Fig. 10 that high concentration (500 mg L^{-1}) of anion Cl^- and cation Ca^{2+} hardly affected the removal of phosphate, whereas the presence of NO_3^- , CO_3^{2-} and SO_4^{2-} resulted in slightly decreased phosphate removal, leading to a decreased phosphate removal from 73.08% to

Table 2 Kinetic parameters for removal of phosphate by AC, Fe/C precursor and $\text{La}^{0.005}\text{@Fe/C}$

Parameters		Adsorbent		
		AC	Fe/C precursor	$\text{La}^{0.005}\text{@Fe/C}$

Fig. 9 Isotherm modeling of (a) Langmuir, (b) Freundlich, and (c) Temkin adsorption isotherms for phosphate adsorption on $\text{La}^{0.005}\text{@Fe/C}$.

55.86%, 53.62% and 62.85%, respectively. This slight decrement of phosphate adsorption capacity in the presence of coexisting anions could stem from the fact that anions can act as a competition ion, inducing electrostatic repulsion between the deprotonated surface hydroxyls and the highly charged PO_4^{3-} . The reduction of phosphate adsorption in the presence of CO_3^{2-} was relatively more obvious, which might be due to the formation of $\text{La}_2(\text{CO}_3)_3$, for it has a lower K_{SP} (3.98×10^{-34}) than LaPO_4 (3.70×10^{-23}).⁵⁴ It can be noticed that the removal of phosphate was effective (>53.62% removal efficiency) even in the presence of coexisting ions with 50-fold excess, indicating $\text{La}^{0.005}\text{@Fe/C}$ had a high adsorption selectivity towards phosphate.

3.5 The stability and reusability of $\text{La}^{0.005}\text{@Fe/C}$

To assess the reusability of $\text{La}^{0.005}\text{@Fe/C}$, a series of experiments have been devised, whereby the adsorbent is exposed to thermal regeneration and five cycles of repeated adsorption and regeneration. The performance of the reused $\text{La}^{0.005}\text{@Fe/C}$ with respect to the adsorptive removal of phosphate is shown in

Fig. 11. A gradual decrease from 7.20 mg g^{-1} to 4.20 mg g^{-1} was observed in the phosphate removal capacity, which corresponds to a capacity retention of 58.33% after five cycles. Nonetheless, the adsorbent exhibited higher stability than the previously reported phosphate adsorbents, *i.e.*, $\text{La}(\text{OH})_3/\text{Fe}_3\text{O}_4$ (4:1) nanocomposite, and La based FeCl_3/LSF (lithium silica fume).^{10,55} Therefore, the La@Fe/C particle in this work is considered as a promising phosphate adsorbent with high stability and removal efficiency.

3.6 Comparison with various adsorbents

Table 4 presented the comparison of theoretical phosphate adsorption capacity of $\text{La}^{0.005}\text{@Fe/C}$ with various adsorbents based on Langmuir isotherm. It can be seen that the phosphate adsorption capacity of $\text{La}^{0.005}\text{@Fe/C}$ is relatively higher than the other adsorbents reported in the literature. Similarly, other bi-metallic adsorbents such as Fe–Mn binary oxide and ACF–LaFe reportedly exhibited high phosphate adsorption capacities of 33.20 mg g^{-1} and 29.44 mg g^{-1} , respectively. These high values are associated with the fact that by coupling two metal

Fig. 10 The effect of NO_3^- , Cl^- , CO_3^{2-} , SO_4^{2-} and Ca^{2+} on phosphate adsorption of $\text{La}^{0.005}\text{@Fe/C}$.

Fig. 11 Phosphate adsorption capacity and removal efficiency of $\text{La}^{0.005}\text{@Fe/C}$ as a function of adsorption-regeneration cycles.

Table 4 Comparison of phosphate adsorption capacity of various adsorbents

Adsorbent	Temperature (K)	Adsorption capacity (mg g ⁻¹)	Reference
La ^{0.005} @Fe/C	293	32.36	This work
Activated carbon	298	8.70	47
Iron oxide tailings	293	8.21	48
AC/N-Fe ^(II)	298	14.12	49
AC/N-Fe ^(III)	298	8.13	49
La(III) modified zeolite	293	24.60	50
Fe-Mn binary oxide	298	33.20	51
Granular ferric hydroxide	294	20.9	52
ACF-LaFe	298	29.44	8
Fe ₃ O ₄ @La-Ce	313	19.6	53
Fe ₃ O ₄ nanoparticles	296	4.50	10
Magnetic Fe ₃ O ₄ @SiO ₂ @La ₂ O ₃	296	27.80	10

species, the adsorbent interface could be engineered to possess multiple sites which then contribute to binding phosphate.⁵⁶

4. Conclusions

A novel 3D flower-like La@Fe/C magnetic composite adsorbent was successfully prepared by carbothermal reduction of ilmenite *via* microwave radiation. The resultant La^{0.005}@Fe/C features active adsorption sites for phosphate uptake even in the presence of 50-fold excess competing ions. The phosphate adsorption on La^{0.005}@Fe/C fitted well to Langmuir mode, with the calculated maximum adsorption capacity of 32.36 mg g⁻¹ at 293 K. Thermodynamic study indicated that the adsorption of phosphate occurs spontaneously and endothermically. Regeneration tests showed the La@Fe/C composite is a potentially attractive adsorbent for the removal of phosphate from aqueous solutions with high efficiency and recycling capability.
