Recent advances in the green processing of organic photovoltaic devices from nanoparticle dispersions

Mohammad Rammal,^a Patrick Lévêque,^{ib} Guy Schlatter,^{ib} Nicolas Leclerc^{ib}*^a and Anne Hébraud^{ib}*^a

Two decades of research have allowed organic solar cells to appear today as an alternative to hybrid and inorganic photovoltaic devices. However, several issues need to be addressed in order to facilitate their production on an industrial scale. Active layer processing is one of them. Indeed, high power conversion efficiency organic semiconductors are poorly soluble and require not only the use of toxic solvents but also moderate temperature (above 80 °C) processing for which the amount of generated vapors is critical. Recently, the use of conjugated polymer nanoparticle (NP) dispersions in water or alcohols has emerged as a possible solution to avoid toxic solvents. Recent studies have demonstrated that it is possible to finely tune the active-layer morphology using NPs and achieve high power conversion efficiencies. In this review, we aim at providing an up-to-date overview of this field by focusing on the different steps that make up the development of an organic photovoltaic device, from the preparation of nanoparticles to the characterization of the device. Finally, we provide perspectives for the future development of organic photovoltaic devices using a NP-based active layer.

1. Introduction

The development of renewable energy, reducing CO₂ emissions and natural resource consumption, is a key challenge to limit global warming. In this context, major efforts are being made to increase the performance of photovoltaic panels and improve their life cycle in terms of energy payback time (EPBT) and environmental loads.¹ Among the different photovoltaic

**Mohammad Rammal**

Mohammad Rammal obtained his Master of molecular and macromolecular chemistry degree from the University of Bordeaux (France) in 2017. The same year, he began his PhD under the supervision of Dr Anne Hébraud at the Institute for Chemistry and Processes for Energy, Environment and Health ICPEES in Strasbourg. His research interests focus on the development of new eco-friendly optoelectronic devices based on organic polymer nanoparticles.

**Patrick Lévêque**

Patrick Lévêque received his PhD in Materials Science from Poitiers University (France) in 1998. After completing his post-doctoral research at KTH-FTE in Bengt G. Svensson's team in Stockholm (Sweden) on defect engineering in inorganic semiconductors, he joined the ICube laboratory of the University of Strasbourg (France) as an associate professor in 2004. His research interests have focused on the charge-carrier dynamics in organic semiconductors and on organic photovoltaics since 2006.

technologies, organic photovoltaics (OPVs) look appealing. OPV performances, now reaching 18% at the laboratory scale,² are still below those of mono- and poly-crystalline based silicon photovoltaics. OPVs have nevertheless several advantages as

OPV modules are light weight and flexible, their shape and color can easily be tuned and they can be produced at low cost by solution processes requiring lower energy. In recent years, the increase of the Power Conversion Efficiencies (PCE) of OPV devices has been achieved thanks to the evolution of photoactive material design on the one hand and the improvement of the different device sub-layers on the other hand.

Regarding photoactive materials, in order to meet industrial criteria, two key concerns remain to be addressed: (i) their synthesis cost, closely related to the number of steps and reagents used, and (ii) their processing in thin-films. If the first point starts to be well documented with in particular the recent introduction of the following new indexes: the synthetic complexity (SC) and the figure of merit (FOM),^{3,4} the second point still needs to be addressed as high PCE organic semiconductors (OSCs) are less and less soluble and require not only the use of toxic organic solvents but also moderate temperature (above 80 °C) processing where the amount of generated vapors is critical.^{5,6} Therefore, the development of alternative eco-friendly processing allowing the use of green solvents appears as a key step towards industrialization of OPV technology. Three main solutions are currently being developed consisting of (i) research on alternative and less toxic solvents,⁷ (ii) the design of water soluble materials⁸ and (iii) the

Guy Schlatter

Guy Schlatter received his PhD in materials science in 1995 from Mines ParisTech, France. After completing his postdoctoral research at Ecole Polytechnique of Montréal, Canada, he was appointed as an assistant professor at the University of Strasbourg, France. Since 2007, he has been a full professor at the European Engineering School of Chemistry, Polymers and Materials, University of Strasbourg.

His research interests focus on the micro and nano-fabrication of polymer systems as well as electrospinning with an emphasis on the understanding and the control of material organization during the process of fabrication.

Nicolas Leclerc

Nicolas Leclerc received his PhD from the Pierre and Marie Curie University (Paris, France) in 2003. After completing his post-doctoral research at Laval University in Mario Leclerc's team (Canada), he joined the ICPEES institute of the University of Strasbourg (France) as a CNRS researcher in 2005. His research interests focus on the development of new molecular and macromolecular organic semiconductor materials and

their applications in optoelectronics, mainly in the fields of photovoltaics and thermoelectricity.

Anne Hébraud

Anne Hébraud obtained her PhD from the Pierre and Marie Curie University (Paris, France) in 2004. After a post-doctoral fellowship in the group of Katharina Landfester at the University of Ulm (Germany), she was appointed assistant Professor at the University of Strasbourg in the ICPEES institute. Her research interests focus on the physico-chemistry of polymers and their use in the elaboration of colloids and nanofibers for diverse applications.

dispersion of OSC nanoparticles (NPs) in water or alcohols, resulting in an eco-friendly active layer ink.

Two recent reviews have been published discussing these three different strategies,^{9,10} but none of them described thoroughly all the aspects of the NP dispersion route. Our review focuses on the NP dispersion strategy and aims at describing its different steps, from the elaboration of the NPs to their assembly in the active layer, the OPV device characterization and its optimization. It also highlights the essential parameters that can be tuned at each step to improve the performance of the final device.

Regarding the device sub-layer optimization, the NP approach also allows one to specifically address the control of the active-layer thin film morphology in an innovative way. Indeed, the photoactive layer of efficient solution-processed OPV devices is made of phase-separated domains of electron-acceptor (A) and electron-donor (D) materials known as bulk heterojunctions (BHJs, Fig. 1). Two different levels of organization should be considered. First, the structuration of the materials in each domain at the molecular scale (crystallinity, self-assembly properties, *etc.*) is a major parameter to obtain high charge-carrier mobilities. Then, at the mesoscale, the morphology of the phase separation is critical as it simultaneously enables both exciton dissociation and free-charge collection. The ideal structure is an interpenetrating network of the two phases with a typical length scale of the order of the exciton diffusion length, *i.e.* 10–20 nm. The two levels of organisation of the active-layer depend on the materials' physico-chemical properties (solubility, planarity, self-assembly properties, *etc.*) and on the film preparation process. The elaboration of separate electron-donor NPs and electron-acceptor NPs or composite NPs containing both materials is an attractive way to address these issues, because it provides the possibility to control the morphology of the molecules and their phase separation at the scale of the nanoparticles. These NPs are then assembled to form the active layer. Accordingly, the NP

approach offers an additional control degree over the active-layer morphology.

In this review, we aim at providing an up-to-date overview of this field by focusing on the different steps that make up the development of an OPV device, from the preparation of nanoparticles to the characterization of the device (Fig. 2). Thus, in the first part of the review, we focus on the elaboration of separate and composite OSC NPs by the two main post-polymerization processes: miniemulsion and nanoprecipitation. We then discuss the impact of the materials and different processing parameters on the diameter and internal morphology of these NPs. In the second part, we present the different NP deposition processes and their optimization from spin-coating at the lab scale, to roll-to-roll processing allowing the preparation of large-scale devices. The morphology of the active layer obtained from the assembly of the NPs is then described in detail and the influence of thermal annealing on the purity and size of the segregated donor and acceptor domains is discussed. Finally, the last part of the review focuses on the performances of OPV devices obtained by this strategy. The charge-carrier generation and recombination dynamics, which may limit NP OPV devices, as well as the optimization processes, are extensively discussed.

2. Elaboration of nanoparticle dispersions in green solvents

Different ways have been used to synthesize semiconducting polymer NPs by polymerization in heterophase systems or post-polymerization methods.^{11,12} We focus here on the post-polymerization preparation methods because they are very versatile, allowing the preparation of NPs from most recent organic semiconducting materials. Readers interested in the heterophase polymerization strategy can refer the review of Pecher *et al.*¹¹

Fig. 2 Scheme of the NP dispersion route to OPV cells.

Two main post-polymerization processes can be used to prepare semiconducting NPs with diameters in the range of 20 to 200 nm: miniemulsion and nanoprecipitation.

2.1. The miniemulsion technique

Preparation of aqueous dispersions of semiconducting polymer NPs by the miniemulsion process was first demonstrated by Landfester *et al.*¹³ In this process, two non-miscible phases are prepared: an organic phase composed of the polymer in a good solvent and an aqueous phase containing a surfactant (Fig. 3). The organic phase is then dispersed in the aqueous phase by ultrasonication, giving a metastable miniemulsion, *i.e.* a dispersion of very small organic droplets in an aqueous phase. After evaporation of the organic solvent, a polymer dispersion is obtained. The diameter of the obtained NPs, typically between 50 and 250 nm, depends on the surfactant concentration, with an increase of the surfactant concentration resulting in a decrease of the NP size.¹³ Moreover, as the NPs are obtained after evaporation of the solvent from the miniemulsion droplets, the NP size also increases with the initial polymer concentration in the organic phase.¹⁴ If low boiling temperature (T_b) solvents such as chloroform ($T_b = 61\text{ }^\circ\text{C}$) are usually preferred for the miniemulsion technique, it was also possible to prepare NPs from high boiling point solvents such as *ortho*-dichlorobenzene (*o*-DCB, $T_b = 178\text{ }^\circ\text{C}$)¹⁵ or *o*-xylene ($T_b = 144\text{ }^\circ\text{C}$),¹⁶ thus expanding the range of semi-conducting polymers that can be processed by this technique. In this case, evaporation of the solvent is completed after several hours at 60 or 75 $^\circ\text{C}$ and water has to be regularly added into the flask in order to compensate for water loss through evaporation. Using this process, composite NPs containing two different materials in the same particle can also be prepared, by mixing the two materials in the initial organic phase, prior to emulsification.^{17,18}

Material segregation in NPs. During the solvent evaporation step in the miniemulsion process, phase separation then occurs inside the NPs leading to core-shell,¹⁹ Janus,²⁰ or more complex structures.²¹ The morphology of the NPs can be inferred from Small Angle Neutron Scattering (SANS)^{14,21} or Scanning Transmission X-ray Microscopy (STXM) for large particles (Fig. 4).²² The latter, based on the measurement of

the near-edge X-ray absorption fine structure (NEXAFS) characteristic of the molecular structures of the materials, also allows one to quantitatively determine the chemical composition of the two segregated phases. Its resolution is of 30 nm approximately.

The internal structure of the NPs depends on the surface energy of the materials, but can also vary with the evaporation kinetics or other processing parameters. In general, the materials with higher surface energy are found in the core of the NPs. Thus, when **PCBM** is used in combination with an electron donor polymer, the NPs obtained by miniemulsion have usually a core-shell morphology with the fullerene derivative in the core and the conjugated polymer in the shell. It is the case of **PCDTBT:PC₇₁BM** NPs, **PC₇₁BM** having a higher surface energy (48 mJ m^{-2}) than **PCDTBT** (37 mJ m^{-2}),¹⁴ or of **P3HT:PC₆₁BM**¹⁹ with surface energies of 38.2 mJ m^{-2} ²³ and 26.9 mJ m^{-2} ²⁴ for **PC₆₁BM** and **P3HT**, respectively (see the structures in Fig. 5). Moreover, the size and composition of the two segregated phases, usually not pure, depend on different parameters. The molar mass of the polymer has a limited impact on the composition of the two phases after elaboration. However, it changes the fullerene derivative diffusion during annealing as discussed later in Section 3.2. Indeed, for **P3HT:PC₆₁BM** NPs,¹⁹ variation of the molar mass of **P3HT** between 9 and 72 kg mol^{-1} did not change significantly the composition of the core and shell, as obtained just after the miniemulsion process. The **P3HT**-rich shell contained $72 \pm 5\%$ **P3HT** and the **PC₆₁BM**-rich core contained $73 \pm 12\%$ **PC₆₁BM**. Only for the lowest studied **P3HT** molar mass of 5 kg mol^{-1} was the particle fully blended with a composition of $54 \pm 6\%$ **P3HT** and $46 \pm 6\%$ **PC₆₁BM**. The impact of the ratio of the two materials on the morphology of the NPs was demonstrated by Holmes *et al.*²⁵ Indeed, an increase of the **PC₆₁BM** content in the **P3HT:PC₆₁BM** NPs from 1:0.5 to 1:2 slightly increased the radius of the **PCBM**-rich core, while maintaining its composition at around 70% **PC₆₁BM**. However, a favorable increase in the amount of **PC₆₁BM** in the **P3HT**-rich shell from 18 to 33% before annealing was obtained, reaching 46% after annealing, which is higher than the percolation thresholds in bulk films.²⁶ Moreover, the phase separation and composition of the core and shell depend also logically on the nature of the materials and their miscibility. By STXM, Dam *et al.*²⁷ have

Fig. 5 Chemical structures of **P3HT**, **PCDTBT**, **PSBTBT**, **DPP-SVS**, **PNDI-TVTV**, **PC₆₁BM**, **PC₇₁BM** and **ICBA**.

compared the structure and composition of **P3HT:PC₇₁BM** and **PSBTBT:PC₇₁BM** NPs prepared by miniemulsion, with the same 1:1 blend ratio and a similar NP radius. **PSBTBT** is a highly crystalline low band gap polymer (Fig. 5). They showed that while the radius of the core and the composition of the polymer-rich shell were similar, the purity of the **PC₇₁BM**-rich core was very different with 80% **PC₇₁BM** in the core of **P3HT:PC₇₁BM** NPs and only 60% **PC₇₁BM** in the core of **PSBTBT:PC₇₁BM** NPs. Finally, in the case of 1:1 **P3HT:ICBA** NPs, **ICBA** being a **C₆₀**-bis-adduct

derivative (Fig. 5) highly miscible in **P3HT**, a core-shell structure was still obtained, due to the difference in the surface energy of the two materials, but with a large core containing 41% **ICBA** and a thin shell region containing only 23% **ICBA**. However, after annealing and due to this higher miscibility, the core-shell structure was quickly lost and the NPs became homogeneously blended.²⁸

Influence of the solvent. Varying the quality and evaporation rate of the solvent used to prepare the NPs by miniemulsion

also has an impact on the morphology of the NPs, both for the aggregation of polymer chains and for phase separation processes. As an example, Nagarjuna *et al.*²⁹ have prepared **P3HT** NPs by emulsification of **P3HT** solutions in chloroform, a good solvent for **P3HT** with a boiling point of 61 °C, or toluene, a marginal solvent for **P3HT** with a boiling temperature of 110 °C, or a mixture of both. Evaporation of the solvent was conducted at 80 °C. They showed that the solvent did not change the amount of obtained aggregated phase (*versus* amorphous phase), but it affected its crystalline order *i.e.* the dispersity of crystals (size, shape, order, *etc.*). Indeed, during the organic solvent evaporation process at 80 °C, chloroform evaporated very fast and with no solvent annealing period, leading to a higher degree of dispersity in the polymer aggregates. In the case of toluene, because of a higher boiling temperature and consequently a slower evaporation rate, the aggregates probably started to form before complete evaporation of the solvent and may subsequently be annealed in the presence of residual solvent, leading to tighter packing of the polymer chains. Finally, the NPs obtained from mixed solvents exhibited crystalline regions with a higher degree of uniformity and structural order, thanks to the combination of slow evaporation and the presence of a good solvent. Marks *et al.*³⁰ have prepared **P3HT:PC₆₁BM** by miniemulsion, starting from chloroform solutions. They showed that rapid evaporation under a vacuum led to core-shell NPs with more mixed phases, the purity of the PCBM-rich core decreasing from 79% for slow evaporation to 60% PC₆₁BM, and the purity of **P3HT**-rich shell decreasing from 70% to 64%. Moreover, the crystallinity of **P3HT** was also slightly lower when the chloroform evaporation was rapid, due to a reduced time for the materials to self-organize in the NPs.

Choice of the surfactant. One of the drawbacks of the miniemulsion technique is the use of a surfactant. Most of

the time, an anionic surfactant, sodium dodecyl sulfate (**SDS**, see the structure in Fig. 6), is used in order to decrease the interfacial tension between the organic phase and water, favoring emulsification, and to stabilize the NP dispersion over long periods of time. However, in the active layer, this surfactant interferes with the charge transport (see the discussion in Section 4.3). Therefore it has to be removed before processing the film, by repeating numerous centrifugation dialyses or crossflow ultrafiltration steps.³¹ Cho *et al.*³² have tried to find general rules to choose the best surfactant for miniemulsion preparation. They studied 18 different surfactants, either anionic (with sulfate moieties), cationic (with ammonium groups) or non-ionic (with ethoxylated chains) (Fig. 6). They prepared NPs of a naphthalene tetracarboxydiimide-base n-type polymer semiconductor (**PNDI-TV1**, Fig. 5) and compared the NP sizes, the stability of the dispersions, the crystallinity of the polymer in the NPs and the efficiency of surfactant removal by washing the prepared film in ethanol. They found that surfactants with large aromatic tails did not interact efficiently with the polymer, compared to surfactants with linear alkyl chains, which lead to strong van der Waals interactions with the pendant linear alkyl chains of the polymer. Moreover, nonionic surfactants were also less efficient to stabilize the NPs, resulting in larger particle sizes, even if in a previous paper they had successfully prepared diketopyrrolopyrrole-based polymer (**DPP-SVS**, Fig. 5) NPs of 200 nm diameter with a C₁₂E₄ (C_nE_m alkyl-ethoxyethyl, Fig. 6) surfactant, producing films with high charge carrier mobility.³³ C₁₂-alkyl trimethyl ammonium bromide (C₁₂TAB, Fig. 6) was found to be the surfactant that allowed the preparation of the smallest particles with a minimum excess of surfactant, which was almost completely removed from the final film by ethanol washing. Finally, they also showed that an increasing alkyl tail length led to better packing of the polymer chains in the particles and thus a higher charge mobility in the

Fig. 6 Chemical structures of surfactants used in the miniemulsion process.

final film. Tan *et al.*³⁴ also showed that the conjugation of an anionic surfactant similar to SDS had an impact on the packing of P3HT in NPs. An increase of the conjugation of the surfactant from SDS to sodium dodecylbenzenesulfonate (SDBS, Fig. 6) and disodium 4-dodecyl-2,4'-oxydibenzene sulfonate (DOBS, Fig. 6) led to an increased chain order and conjugation-length of P3HT and a red-shifted absorbance spectrum. Fleischli *et al.*³⁵ have explored the use of two diblock copolymers made of poly(*n*-butylacrylate) or poly(2-(dimethylamino)ethylmethacrylate) and poly(methyl(ethoxyethyl)_n methacrylate) for the preparation of P3HT NPs. They have shown that by varying different parameters (*i.e.* the macrosurfactant and the processing conditions, the organic solvent, the dissolution of the surfactant in the organic or aqueous phase, *etc.*) they were able to tune the optical properties of the NPs and the molecular arrangement of the P3HT chains in the NPs from H- to J-like behavior. Another strategy to prepare NPs was to modify part of the donor or electron acceptor materials to make them amphiphilic and use them as a surfactant. Kim *et al.*³⁶ have grafted polyethylene glycol chains on fullerene to obtain a PEG-C₆₀ surfactant (Fig. 7A). They have shown that this surfactant forms micelles of 2.6 nm radius in water under vigorous agitation, micelles which aggregate further to form 15 nm size clusters. By mixing this aqueous PEG-C₆₀ solution with an organic phase of P3HT in chlorobenzene, and after homogenization and evaporation of the solvent, they obtained NPs with diameters of 30 to 72 nm, decreasing with increasing PEG-C₆₀ concentration. The NPs were composed of a P3HT core surrounded by the PEG-C₆₀ shell. Finally, OPV devices were prepared with these particles, resulting in a PCE of 2.62%, higher than P3HT:PC₆₁BM particles prepared with non-ionic C₁₆E₁₀ surfactant (1.68%), or with SDS (1.37%). In another paper,³⁷ they proposed to increase the electronic charge density of the shell of the NPs, in which the

C₆₀ groups are surrounded by PEG moieties, by adding PC₆₁BM molecules in the shell of the particles. Two preparation protocols were discussed, leading to different particles with more or less PC₆₁BM in the shell (Fig. 7A), thus successfully increasing the charge separation properties of the particle and the PCE to over 5%. On the contrary, Subianto *et al.*³⁸ chose to use a surfactant close to the electron donor polymer, 2-(3-thienyl)ethoxybutylsulfonate sodium salt (TEBS, Fig. 7B), to prepare P3HT:PC₆₁BM NPs by miniemulsion. The NPs were slightly larger than the ones stabilized by SDS, but UV-visible spectroscopy and SANS results revealed a different structure. While NPs stabilized with SDS had a core-shell structure, the ones stabilized with TEBS showed a more homogeneous structure with multiple domains of PC₆₁BM and P3HT (Fig. 7B), which should be favorable to increase the percolation of PC₆₁BM and P3HT domains in the final OPV active layer.

2.2. Nanoprecipitation

The nanoprecipitation technique is the second way to prepare OSC NPs in an aqueous or alcohol based non-toxic solvent. A polymer solution in an organic solvent is injected into a non-solvent of the polymer, miscible with the initial solvent (Fig. 8A). The solubility of the polymer decreases and the system becomes supersaturated. At low supersaturation, in the metastable region between the binodal and spinodal lines of the phase diagram, particle formation takes place through nucleation and growth, whereas for high supersaturation in the spinodal region, the systems demixes spontaneously³⁹ (Fig. 8B). The organic solvent is then evaporated. The advantage of this technique, as compared to the miniemulsion evaporation process, is that no surfactant is needed. However, the NP dispersions tend to aggregate during long-term storage and the formation of stable small NPs is usually obtained in the

Fig. 7 (A) TEM image of a core-shell NP stabilized by PEG-C₆₀, the core is composed of P3HT and the shell of PEG-C₆₀ micelles mixed with various amounts of PC₆₁BM. Fig. 8 (A) Scheme of the nanoprecipitation process, and (B) phase diagram of the OSC/solvent/non-solvent system showing the concentration zone in which stable NPs are obtained.

binodal region at very low polymer concentrations, leading to very dilute dispersions. Moreover, to obtain dispersions in water or in alcohol, the choice of suitable solvents is limited to miscible ones such as tetrahydrofuran (THF) or chloroform.

Wang *et al.*⁴⁰ studied the aggregation-driven growth of the NPs in the first hours after their nucleation, as a function of the structure of the polymer. They compared the aggregation behavior of poly(bithiophene-*alt*-azulene) bearing either alkyl (alkyl-PTA) or alkoxy side chains (alkoxy-PTA) during its nanoprecipitation from chloroform solution into methanol (Fig. 9a). The diameter of alkyl-PTA NPs increases from 60 nm, 1 min after vigorously mixing the 10^{-5} M polymer solution in chloroform with an equal volume of methanol, to 400 nm after 4 h,

after which the NPs became polydisperse. In the case of alkoxy-PTA, a smaller initial diameter of 30 nm was obtained. The NP diameter increased slightly up to 130 nm after 5 h but kept a very low dispersity (Fig. 9). To explain the difference between these two behaviors, the authors observed the evolution of the UV-visible absorption spectra with time and concluded that the electron donation to the conjugated polymer backbone is enhanced for alkoxy groups as compared to alkyl groups, resulting in stronger π - π stacking of the polymer backbone. Thus, alkoxy side chains favor the nucleation step, leading to an increased number of smaller NPs and faster consumption of the free macromolecules. This example illustrates the mechanism of nucleation and growth of the nanoprecipitate. Moreover, as in the

Fig. 9 (a) Chemical structures of poly(1,3-bis[2-(3-*n*-decylthienyl)]azulene) ($C_{10}H_{21}$ -PTA) and poly(1,3-bis[2-(3-*n*-dodecoxythienyl)]azulene) ($C_{12}H_{25}O$ -PTA). Time-dependent size evolutions of conjugated polymer nanoparticles in 1 : 1 mixed chloroform/methanol solutions containing (b) 10^{-5} M $C_{10}H_{21}$ -PTA and (c) 10^{-5} M $C_{12}H_{25}O$ -PTA. case of miniemulsion, several processing parameters, such as the solvent or the relative concentration of species, may also influence the size of the NPs, as well as their crystallinity. Millstone *et al.*⁴¹ have prepared **P3HT** NPs by nanoprecipitation from chloroform polymer solutions into ethanol. They have shown that the final diameter of the NPs increases from 30 to 83 nm with the initial concentration of **P3HT** in chloroform increasing from 0.005% to 0.5%. Moreover, when using monodisperse regioregular **P3HT** synthesized by Grignard metathesis, they obtained NPs with anisotropic shape due to their high crystallinity. As in the case of the miniemulsion technique, composite NPs can also be prepared by nanoprecipitation, starting from a solution containing both electron donor and acceptor materials further mixed with a non-solvent of the two materials. In this case also, the processing parameters allow one to control the size and stability of the prepared NPs. Using a high-throughput engineering method with a robot, Xie *et al.*⁴² investigated systematically the effect of the different processing parameters on the size and stability of **P3HT:ICBA** NPs precipitated from chloroform solutions into five different alcohols with increasing alkyl chain length from ethanol to *cis*-3-hexen-1-ol. They also showed that, whatever the used alcohol, increasing the material concentration in chloroform, from 0.1 to 20 mg mL⁻¹, raised the NP diameter from around 20 nm to 100 nm. The nature of the alcohol had a smaller impact on the NP diameter, which decreased slightly with the length of the alkyl chain. However, it had an important impact on the surface charge density of the NPs and, consequently, on the stability of the dispersion over time. Indeed, NPs produced in a more polar solvent, like ethanol, acquired a higher zeta potential, resulting in more electrostatic repulsion and better stability, as compared to NPs dispersed in *cis*-3-hexen-1-ol, which aggregated within less than 24 h. Finally, they observed a tendency of the diameter of the NPs to decrease with an increasing content of **ICBA** in the NPs, which could be due to a difference in solubility of the two components leading to a difference in the number of nuclei formed during the nucleation period.

Phase separation. Composite NPs obtained from a low band gap donor (LBG) polymer with fullerene-derived acceptor, **PCDTBT:PC₆₁BM** NPs, have been prepared by nanoprecipitation from THF solutions into water (Fig. 5).⁴³ The presence of the two materials in the same particles could be demonstrated by the photoluminescence quenching of the composite NP dispersion as compared to the single **PCDTBT** NP dispersion. Clifton *et al.*⁴⁴ have used steady-state absorption and fluorescence spectra combined with femtosecond transient absorption spectroscopy to infer the internal morphology of regioregular **P3HT:PC₆₁BM** NPs obtained by nanoprecipitation from THF solutions in water. By applying an exciton diffusion model to the transient absorption signal, they showed that **rr-P3HT:PC₆₁BM** particles contained semi-crystalline **P3HT** domains of a size of around 5 nm dispersed in particles containing 5 to 50 wt% **PC₆₁BM**. Schwarz *et al.*⁴⁵ used the same technique to compare the structure of **P3HT:PC₆₁BM** NPs obtained by nanoprecipitation or by miniemulsion. They showed that **P3HT** domains in composite NPs prepared by miniemulsion contained ca. 57% aggregated **P3HT** domains with higher crystalline quality

and larger conjugation lengths than NPs obtained from nanoprecipitation, which contained only 45% **P3HT** domains as aggregated material with poorer crystalline quality. The crystallinity of **P3HT** in the nanoprecipitated NPs was similar to unannealed **P3HT:PC₆₁BM** films cast from chloroform solutions, while the morphology of the NPs obtained by miniemulsion could be compared to films cast from chloroform solutions and annealed at 160 °C. In the case of nanoprecipitation, the materials have less time to rearrange as compared to miniemulsion, in which a kind of solvent annealing occurs. The phase separation into NPs has been studied by SANS with contrast variation for composite **P3HT:ICBA** NPs prepared by nanoprecipitation from chloroform solution into methanol.⁴⁶ It was confirmed that the two materials were homogeneously distributed in the NPs having a diameter of around 100 nm. By SANS, it was not possible to observe phase separation down to the 10 nm size observable by this technique. However, transient absorption spectroscopy revealed long-lived (up to 20 ps) stimulated emission of **P3HT** singlet excitons, being consistent with a degree of **P3HT** and **ICBA** phase separation in the NPs. The nanoprecipitated NPs thus contain uniformly dispersed domains smaller than 10 nm. In order to prepare core-shell NPs by nanoprecipitation, Chambon *et al.*^{47,48} performed the sequential double nanoprecipitation of **P3HT** and **PC₆₁BM**. They first started from a solution of **P3HT** and **PC₆₁BM** in THF and triggered the nanoprecipitation of the **P3HT** core in dimethyl sulfoxide (DMSO), in which **PC₆₁BM** is soluble enough to remain in solution. In a second step, this dispersion was added to water, inducing the precipitation of a **PC₆₁BM** shell surrounding the **P3HT** core of the NPs. They thus obtained **P3HT:PC₆₁BM** core-shell NPs of 80 to 100 nm in diameter, depending on the starting concentrations, whose variation is however limited by the low solubility of **PC₆₁BM** in DMSO.

Compared to the miniemulsion process, simple nanoprecipitation normally allows the formation of more uniform phase separation inside the NPs without the use of a surfactant, which makes it very attractive for OPV applications. However, the production of small NPs with low dispersity in size and good stability over time is a real challenge. Moreover, its success depends on the material/solvent/non-solvent phase diagram, which is different for each molecule, the stable dispersion being obtained in the binodal region at very low polymer concentration, yielding very dilute NP dispersions. Recently, Xie *et al.*⁴⁹ developed a surfactant assisted nanoprecipitation method which allows the synthesis of stable dispersions at higher concentrations in the spinodal region and is therefore more versatile regarding the nature of the materials. As a surfactant, they cleverly chose Pluronic F127 (Fig. 6), a thermo-sensitive block copolymer of ethylene glycol and propylene glycol. It has the advantage of being non-ionic. Moreover, its solubility in water increases at low temperature. F127 could therefore be easily stripped off from the NPs at 4 °C in a few centrifugation dialysis steps, much more efficiently than for **SDS** removal (Fig. 10). With this technique, they prepared composite NPs of **P3HT** and a non-fullerene acceptor (NFA) **o-IDTBR** (Fig. 10a), starting from a 5 mg mL⁻¹ material solution in THF followed by precipitation into water with a

Fig. 10 (a) Chemical structures of **ITIC**, **o-IDTBR**, **PCE-10** and **PBQ-QF** used to prepare NPs by surfactant-assisted nanoprecipitation. (b) Pluronic F127 is a copolymeric surfactant with a temperature-dependent critical micelle concentration (cmc). After elaboration of the NPs at room temperature, the dispersion is cooled down to 0 °C. At this low temperature, the surfactant becomes more soluble in water, its cmc increases and it desorbs from the NP surface. It can then be easily removed by centrifugal dialysis in a few steps only. high solvent:non-solvent ratio of 1:2, whereas it is usually in the range of 1:8 or lower in standard nanoprecipitation. Such a strategy resulted in a dispersion having a higher final NP concentration than what it is usually achieved in classical nanoprecipitation. Moreover, after surfactant stripping, the NP dispersions remained stable for more than 3 months. Finally, the authors demonstrated the versatility of this technique by preparing dispersions of composite NPs with two LBG polymers PCE10 or PBQ-QF, and two NFAs, o-IDTBR or ITIC (Fig. 10a), which have been used in OPVs to reach a record efficiency for NP based systems of 7.5%.

3. Building the active layer by NP assembly, and its resulting morphology

Once synthesized, the NPs have to be assembled into a functional active layer. As already described, the ideal morphology of the film is a two phase bicontinuous structure with percolating pathways allowing the efficient conduction of electrons and holes towards the electrodes (Fig. 1).

The elaboration of an active layer from an NP ink is performed in two steps: first, the deposition and assembly of the solid NPs during solvent evaporation and then an annealing step allowing the diffusion of the materials in the interparticle voids, leading to more compact and smooth active layers. Rearrangement of the donor and acceptor phases can also

occur during annealing. These two steps can then be repeated several times in order to obtain a thicker and/or a multilayered film.

3.1. Processes used to build an active layer from NP dispersions

Different processes have been used to build a film from the NP dispersions for the preparation of active layers from the laboratory scale to the industrial one. Several issues are encountered. Among them, one can cite the low solid contents of the prepared aqueous dispersions (Table 1) requiring additional concentration steps, and their low viscosity leading to low film thicknesses. It is then often necessary to repeat the deposition step in order to increase the active layer thickness. Another difficulty is the poor wettability of the aqueous dispersions on more or less hydrophobic substrates, resulting in a non-homogeneous layer with large roughness, responsible for current leakages and failure of the device.

At the lab scale, the main used process is the spin-coating of the NP dispersions. Bag *et al.*⁵¹ have optimized the spin-coating conditions of a P3HT:PC₆₁BM blend in order to obtain a reproducible deposited active layer. Optimization was performed both for separate and composite NPs for a direct PV structure of glass/ITO/PEDOT:PSS/active layer/Ca/Al, the direct structure allowing illumination through a transparent hole-collecting electrode (ITO/PEDOT:PSS). Thus, UV-O₃ treatment of the PEDOT-PSS layer allowed its water contact angle to be decreased to less than 2°, leading to rapid and uniform

Table 1 Examples of solution/dispersion concentrations after preparation and before processing for various OSC systems

spreading of the NP dispersion and a low surface roughness. Better packing of the NPs in the layer was also obtained by spin-coating NPs in a solvent mixture of ethanol:water (20 : 80) rather than water alone, probably thanks to a decrease of the electrostatic repulsion between the NPs, while increasing van der Waals attraction. Moreover, in order to prevent the PEDOT-PSS sublayer from re-dissolving when in contact with the aqueous dispersion, the evaporation of the solvent was sped up by pre-heating the substrate with an IR lamp. An ambient atmosphere was also important as a relative humidity below 30% has also been shown to increase the porosity and roughness of the deposited layer. Finally, the addition of a thin PC₆₁BM buffer layer on top of the active layer, before Ca/Al electrode deposition, reduced the surface roughness to 10 nm and prevented leakage current to the electron-collecting electrode. OPV device characterization clearly highlights the positive effect of this buffer layer, especially on the fill factor (FF), which reached 65%. Although modest, the final PCE of 2.15% is clearly in the average of the PCEs obtained for such P3HT-based blends.⁵⁸

By studying composite NPs made of two fluorene-based polymers, one electron donating derivative, called PFB, and one electron accepting derivative, called F8BT (Fig. 11b), Stapleton *et al.*⁵⁹ have shown that the successive deposition of NPs by spin-coating, with rapid annealing at 70 °C between each layer deposition for drying purposes, allowed one to tune the thickness of the final film. In addition, they observed that the roughness of the film decreased with the number of deposited layers (Fig. 11a). The voids left in the underlying film were filled by the freshly deposited NPs, thus increasing the compactness and quality of the film. However, when the film became too thick, cracks appeared on its surface, probably due to negative capillary pressure between NPs resulting from water removal. Hence, an optimum has to be found for the number of NP deposition layers and thickness of the film in order to achieve the best morphology.

Preparation of large surface devices is not possible by using spin-coating; therefore, other deposition techniques have been studied such as spray coating, ink-jet printing or doctor blading.

P3HT films were prepared by spray coating of aqueous dispersions of P3HT NPs in water leading to NP assemblies with thicknesses up to 1.5 μm.⁶¹ The cleaned ITO substrate was heated at 80–85 °C and a UV-O₃ pretreatment improved the film quality. The presence of surfactant in the dispersion had an important influence on the packing of NPs in the films, leaving voids in the film due to electrostatic repulsion between the particles. Therefore, removal of the excess surfactant, as discussed for the miniemulsion process (Section 2.1), was necessary to obtain close-packed NP assemblies.

Ink-jet printing is an interesting technique that allows the deposition of solar cells with custom-designed shapes, while doctor blading is limited to large surfaces homogeneously coated.⁶² The formulation of the dispersion has to be adapted in order to avoid nozzle clogging for ink-jet printing. As an example, in the case of P3HT:ICBA NP dispersions in ethanol, a higher boiling point solvent, butoxyethanol (boiling point 170 °C), often used in paints, had to be added.⁶⁰ The temperature of the substrate can also be optimized to tune the spreading of the droplets and evaporation rate. If the deposited film is too thin, several layers can also be printed. However, one of the difficulties of this technique is to avoid the coffee stain effect, an accumulation of NPs at the edge of the deposited droplets. Indeed, it leads to the formation of ridges with increased thickness in the final film (Fig. 11c).

Doctor-blading is a deposition technique that closely resembles slot-die coating used in roll-to-roll processes. Sankaran *et al.*⁶⁰ have prepared inverted OPV devices with structure glass/ITO/ZnO/composite NPs/PEDOT:PSS/Ag by doctor-blading active layers of surfactant-free P3HT:ICBA NP dispersions in ethanol onto ZnO. Two blading sublayers were applied before thermal annealing at 150 °C, leading to similar performances to spin coated devices. They also demonstrated the possibility to prepare a device active area of 1.1 cm² with minimal loss of performance from 3.9% for 0.105 cm² to 3.4%. Xie *et al.*⁴² have also prepared inverted OPV devices with structure glass/ITO/ZnO/composite NPs/MoO_x/Ag by doctor-blading P3HT:ICBA NPs in different alcohols on ZnO.

The best device performance was obtained for ethanol with a PCE of 4.26%. Indeed, NPs in alcohol with increasing alkyl chain length up to hexanol showed stronger aggregation and lower wetting on the substrate. Four sequentially blade-coated layers were necessary to obtain an active layer thickness of 240 nm.

OPV active layers have also been deposited onto flexible PET foil from aqueous dispersions of composite conjugated polymer: fullerene derivative NPs by roll-to-roll processing.^{54,63} One of the important issues encountered in the case of slot-die coating of an aqueous dispersion onto a ZnO electron transporting layer (ETL) for inverted structures or a PEDOT-PSS hole transporting layer (HTL) for direct structures is the dewetting of the NP ink before complete drying of the film. This phenomenon can be controlled by fine tuning of the ink formulation. In particular, it was shown that leaving an optimized concentration of **SDS** surfactant in the ink allowed one to control dewetting, but was detrimental to the device performance. Andersen *et al.*^{63,64} have added a non-ionic fluorosurfactant (FSO-100) to the ink formulation. However, in excess, this surfactant could be responsible for low film adhesion to the substrate. Another way to control the interfacial surface energy is to use ozone treatment to change the substrate chemistry. Applied to the PEDOT-PSS HTL, this treatment lowered the water contact angle by increasing the PSS fraction at the surface of the film, resulting in good wetting of the NP ink slot-die coated onto it and thus increasing the homogeneity of the active layer film.⁵⁴ Simultaneous double slot-die coating of the active layer and the PEDOT-PSS HTL onto ZnO was also

demonstrated.¹⁰⁸ In this case, it was shown by film delamination in NaOH solution, and by Time of Flight-Secondary Ion Mass Spectrometry (TOF-SIMS) analysis, that a double layer had been obtained with only limited inter-diffusion between the active and the hole transporting layers, the diffusion of NPs being too slow for the two dispersions to mix before drying. Even if significant process optimization has still to be done in order to increase the device performances, the possibility to prepare NP OPV flexible devices entirely processed by roll-to-roll has been demonstrated with a PCE up to 0.45%.⁵⁴ Roll-to-roll processing of aqueous NP dispersions is thus the most promising route to large scale printing of OPV devices from aqueous solvents.

3.2. Morphology of the BHJ film at the mesoscale

In this part, we discuss the morphology of the active layer composed of both electron donor and acceptor materials, formed by the assembly of the NPs, as building blocks. The phase separation of the two materials is discussed, keeping in mind that the ideal morphology is formed by two percolating material networks allowing exciton dissociation at interfaces and charge transport to the electrodes.⁶⁵ In order to illustrate these features, a correlation with the OPV device performances is also made when it makes sense. In order to make this review as exhaustive and clear as possible, the reader will find in Table 2 the main features associated with the performance of organic photovoltaic devices reported in the literature.

In the following, we discriminate between active layers prepared from a dispersion of composite NPs or from a dispersion of a binary mixture of electron donor NPs and electron acceptor NPs.

Films from a binary mixture of NPs. Many studies have focused on the ordered assembly of a binary mixture of two kinds of NPs. Indeed, some ordered crystalline structures, such as the ALB₂ structure (Fig. 12a and b), could be very interesting for photovoltaic applications because they allow the formation of continuous percolation paths in the vertical direction.⁶⁶ However, this kind of assembly necessitates the use of particles with very low dispersity in diameter and the fine tuning of their interactions: van der Waals attraction, and electrostatic or steric repulsion. Moreover, the preparation of such an ordered assembly also requires a slow sedimentation or particle concentration step in order to give enough time for the spheres to crystallize at volume fractions of 0.49 to 0.55.⁶⁷ For semiconducting NPs usually deposited using rapid processes such as spin-coating, a metastable “disordered” assembly, also called random close-packed (RCP), is obtained (Fig. 12c). In this case, several parameters can be varied in order to optimize the assembly of the two types of particles and thus the final morphology of the film. The main parameters are the proportions of each type of particles and their difference in diameter. Gehan *et al.*⁶⁸ have prepared films from a mixture of P3HT NPs and PC₆₁BM NPs of equal diameter and in equal proportion. The morphology of the film was observed by SEM showing a disordered glassy state. Further selective dissolution of PC₆₁BM in dichloromethane revealed a random mixture without segregation of the two types of particles. Moreover, they used conducting Atomic Force Microscopy (cAFM) to characterize the hole conduction pathways formed by the network of neighbouring P3HT particles percolating through the film. Time of Flight (TOF) mobility measurements in the P3HT phase were also performed, showing a hole mobility of $\sim 8 \times 10^{-5} \text{ cm}^2 (\text{V s})^{-1}$ for films processed from the mixture of P3HT NPs and PC₆₁BM NPs as compared to a hole mobility of $\sim 2 \times 10^{-4} \text{ cm}^2 (\text{V s})^{-1}$ measured for films processed from pristine P3HT solutions or P3HT-only NP dispersions. By using cAFM and TOF, the same group also estimated the percolation limit at $\sim 30\%$ in proportion of particles in a binary assembly of P3HT and polystyrene (PS) NPs.⁶⁹ They found an increase of the conduction pathways and hole mobility, following a power scaling law, with the proportion of P3HT NPs (Fig. 12d–g). For donor:acceptor (D:A) active layers, they found that the optimum P3HT:PC₆₁BM NP ratio was 2:1, with a maximum PCE of 1.84% measured for a direct-structure OPV device. Such a ratio is similar to the ones usually observed in solution processed P3HT:PC₆₁BM devices.⁵⁸

After the deposition step, the random close-packed assembly of NPs still contains voids between the NPs and an annealing step is required to obtain a continuous compact film, by joining the NPs, thus increasing the contact area between the two different phases where exciton dissociation occurs and forming charge conduction pathways, leading to the final film morphology (Fig. 13b).

Kietzke *et al.*¹⁸ have prepared films from a mixture of separate NPs of two fluorescent polymers, one poly(*p*-phenylene)-type

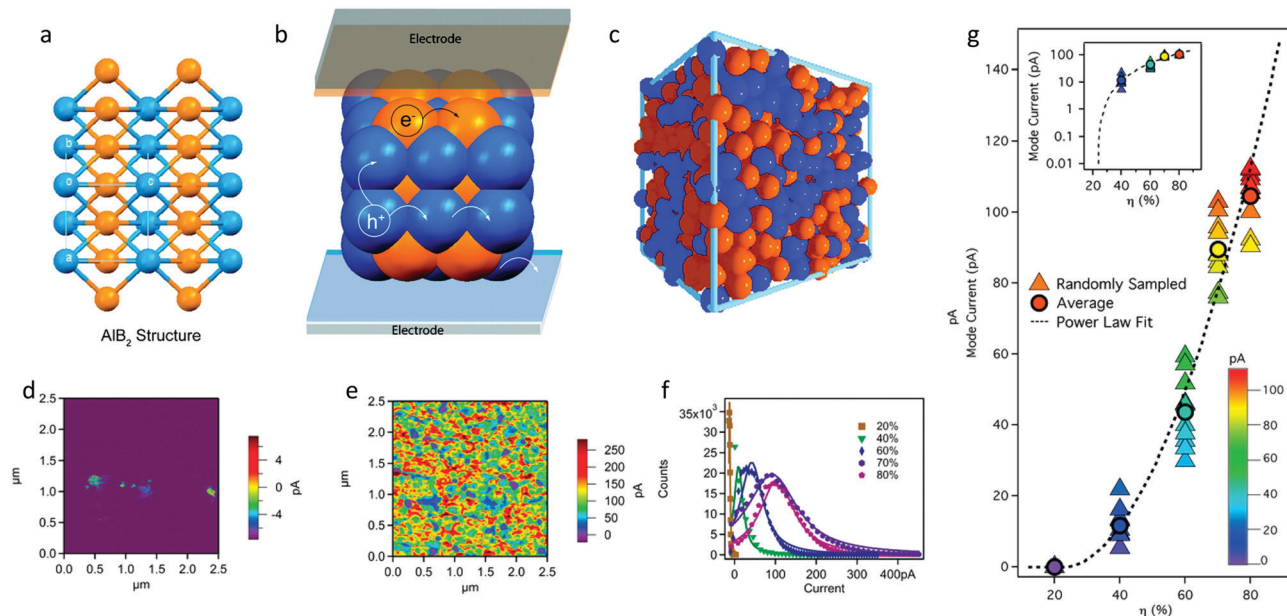

Fig. 12 (a and b) Expanded view of the AIB₂ structure showing continuous pathways for electron/hole transport to the cathode/anode, respectively, and (c) disordered assembly of NPs (RCP). ladder polymer (**m-LPPP**, Fig. 13a) which does not show softening before its high decomposition temperature and one derivative of polyfluorene with T_g close to room temperature. The two polymers were selected to study the morphology of the films by energy-transfer experiments. After deposition by spin-coating, RCP NP assemblies were obtained with partial merging of the soft polymer particles. The film became smoother after annealing at 200 °C, and optical excitation at the absorption wavelength of polyfluorene resulted in quenching of the polyfluorene emission and charge transfer to the **m-LPPP** polymer, whose emission was increased by four, indicating an increase of the interfacial area between these two polymer phases during annealing. A similar phenomenon was observed for a binary mixture of **PFB** and **F8BT** NPs, showing increased energy transfer after annealing of the film slightly above the T_g of the polymers.¹⁸ Holmes *et al.*⁷¹ have prepared binary mixtures of **PC₆₁BM** and **P3HT** NPs. They have shown using STXM and photoluminescence experiments that careful thermal annealing above the T_g of **P3HT** allowed the softening of the NPs, increasing the contact area between them and the diffusion of **PC₆₁BM** into the amorphous parts of the **P3HT** phase, leading to a three-phase microstructure with **P3HT** crystalline domains, **PC₆₁BM** domains and a mixed amorphous third phase containing more than 20% **PC₆₁BM** (Fig. 13b). Diffusion of **PC₆₁BM** into a **P3HT** phase had already been demonstrated in solvent-cast **P3HT:PC₆₁BM** films.^{72,73} This third mixed phase, together with the high crystallinity of **P3HT** allowing a high diffusion length of excitons, resulted in an exciton dissociation efficiency as high as 60%, as compared to 37% before annealing.

Films from composite NPs. In the case of composite particles containing at the same time electron donor and acceptor materials, the morphology of the resulting films is different. The phase separation of domains depends on the particle size²⁰ and on their internal morphology, which can be Janus or core-shell. The most common case of core-shell NPs is not the ideal geometry as it might be difficult to obtain a percolation path of the core material in the film. However, Gehan *et al.*⁶⁸ found a higher PCE (2.15%) for composite nanoparticles of **P3HT:PC₆₁BM** than for binary mixtures of the pristine NPs (1.84%). By cAFM and TOF, they also demonstrated differences in the hole conducting pathways of **P3HT**, which is the shell

material as demonstrated earlier by Holmes *et al.*¹⁹ The composite NP films had a hole mobility on the same order of magnitude as **P3HT**-only NP films in the low-field regime. In the case of core-shell composite particles, thermal annealing of the film plays a fundamental role in the possible connection of the core material domains and the final film morphology. As an example, when using core-shell composite NPs with poly[2,3-bis-(3-octyloxyphenyl)quinoxaline-5,8-diyl-*alt*-thiophene-2,5-diyl] (**TQ1**, Fig. 13a), an amorphous electron donor polymer, as the shell, in combination with **PC₇₁BM** as the core, it was demonstrated that annealing at a moderate temperature of 140 °C, slightly above the T_g of **TQ1**, led to the formation of nano-pathways between the **PCBM** cores of neighboring particles (Fig. 13c), thus allowing the percolation of the core-material in the film.⁷⁴ However, annealing at higher temperatures above 160 °C resulted in the loss of the NP structure with gross phase separation and formation of large **PCBM** aggregates of a few hundreds of nm, which is detrimental to the OPV performance. Indeed, the correlation between phase segregation and the solar cell PCE is particularly obvious in this case since the PCE first increases with temperature, reaching 2.5% at 160 °C, before decreasing sharply at higher annealing temperatures.

In several cases, it was shown that the use of composite NPs, together with mild thermal annealing, is a good way to control the size of the phase-separated domains, even when it was not possible by solution casting. As an example, **PDPP-TNT** (Fig. 14a), a diketopyrrolopyrrole-based electron donor polymer, and **PC₇₁BM** processed in chloroform solutions led to phase segregated morphology with domain sizes reaching the micron scale (Fig. 14b). In contrast, films prepared from composite NPs allowed the morphology of the active layer to be controlled at the nanometer length scale (Fig. 14c) even if mild annealing (at 130 °C for 10 min) was necessary to join the NPs and obtain a working OPV device (1.99% at best).⁷⁵ However, the control of the morphology of the film was lost at higher annealing temperature or longer annealing time, resulting in gross phase segregation of the fullerene outside the particles and a drop of the PCE.

This effect of coarse phase separation was also observed for **P3HT:PC₆₁BM** composite NP films, at a lower annealing temperature of 140 °C for 4 min,⁷⁶ probably due to the lower T_g of **P3HT** as compared to **PDPP-TNT** or **TQ1**. In addition, the

authors demonstrated, by combining optical spectroscopic and microscopic (STXM and TEM) analyses of the thin films, that before annealing, the NP films already show evidence of greater phase segregation and interchain order within the NPs than in unannealed solution cast BHJ films. Consequently, coarse phase segregation occurs very quickly in NP films upon thermal annealing as compared to BHJ films. This clearly suggests that the initial state of the film constituents plays a preponderant role in the thermal annealing effect and thus influences the temperatures and times to be applied. Subsequently, using similar analysis methods and still based on the **P3HT:PC₆₁BM** binary system, the same team⁷⁷ showed the different impact of thermal annealing at 140 °C for 30 min, as a function of the NP preparation process, on the final film morphology. Indeed, while the composite **P3HT:PC₆₁BM** NPs prepared by mini-emulsion exhibit a core-shell structure, the NPs prepared by nanoprecipitation are fully blended. The OPV performances measured on the unannealed as-cast films are similar in both cases. However, upon thermal annealing the core-shell NPs undergo significant phase segregation, leading to micron-sized domains of near-pure **PC₆₁BM** and **P3HT**, while the blended nanoprecipitated NPs melted together without any phase segregation, allowing the conservation of an optimum blended

morphology. Consequently, the charge transport and device efficiency were improved upon annealing. A final PCE of 1.09% for the nanoprecipitated NPs was reported by the authors. As compared to standard **P3HT:PC₆₁BM** spin-coated films, the lower PCE could be mainly attributed to the lower short-circuit current density (J_{sc}) and FF. It can thus be assumed that blended NPs, as obtained by nanoprecipitation, are less prone to coarse phase separation and consequently tolerate harder thermal annealing.

Gärtner *et al.*⁷⁸ have illustrated this point clearly. Indeed, as seen previously, they produced **P3HT:ICBA** blended surfactant-free NPs by nanoprecipitation in MeOH and elaborated multilayer homogeneous thin-films of approximately 250 nm thickness. Subsequent thermal annealing (up to 200 °C) does not show any impact on **P3HT** crystallization as probed by UV-vis absorption spectroscopy. However, this thermal annealing is of crucial importance for the device efficiency, which increases significantly up to such temperatures well above the T_g of the organic materials (Fig. 15). In order to better understand the thermal annealing-OPV device efficiency relationship, the authors investigated the limiting recombination processes by performing intensity dependent photo-current density measurements. Upon thermal annealing, the limiting recombination process changes

from bimolecular to monomolecular. Associated with a simultaneous decrease in film roughness and a significant increase in open circuit voltage (V_{oc}) and FF, the authors suggested that thermal annealing increases the close packing of NPs and therefore facilitates the charge carrier transport and extraction. They thus reached a PCE as high as 4.1%, not so far from the standard of the system having the same composition but deposited from toxic solvent solutions.

4. OPV cells

The development of an effective OPV device is not limited to the processing of a suitable photoactive thin film. Indeed, many chemical and physical parameters have to be taken into consideration, such as the donor:acceptor ratio, the interfacial layers, the type of electrodes or the nature of the optoelectronic components.

4.1. Donor:acceptor ratio

A key parameter in OPVs is the optimum donor:acceptor (D:A) ratio to achieve the most ideal morphology, the right balance between charge carrier mobilities and the best PCE. This ratio usually depends mainly on the nature of the donor and acceptor components and, to a lesser extent, on the deposition parameters such as the solvent, the deposition temperature or the presence of additives. But very often this ratio evolves within a very narrow range of values. For example, when considering the **P3HT:PC₆₁BM** binary blend, it is well established that a suitable ratio is around 1:0.8 by weight.⁵⁸

Interestingly, a few articles show that this optimal ratio can be considerably modified when switching to active layers elaborated from NPs. This is particularly noticeable in the case of core-shell NPs, obtained by mini-emulsion.

Indeed, Holmes *et al.*²⁵ investigated the OPV performances of core-shell NP-based thin films with varied D:A ratio.

In particular, they highlight a PCE evolution, as a function of the **PC₆₁BM** content, that is very different from the trend generally observed in **P3HT:PC₆₁BM** BHJs. Indeed, with a high **P3HT:PC₆₁BM** ratio ranging from 1:1 to 1:2, they observed a constant and relatively high PCE value, while it quickly decreases for a **P3HT:PC₆₁BM** ratio below 1:1 and in particular for the observed 1:0.8 optimum ratio in standard BHJ solar cells. Using a combination of STXM and SEM microscopies, the authors observed that increasing the **PC₆₁BM** proportion does not affect significantly the size of the **PC₆₁BM**-rich core, which is still smaller than the exciton diffusion length, but it has a strong impact on the composition of the initially **P3HT**-rich shell, after thermal annealing. For the annealed 1:0.5 ratio, the joined shell phase consists of less than 20% **PC₆₁BM**, which is below the minimum concentration required to achieve continuous **PC₆₁BM** percolation pathways (percolation threshold) in the bulk film. When increasing the initial NP **PC₆₁BM** content to a ratio over 1:1, the **PC₆₁BM** shell fraction increases to values above 33%, approaching the optimum blend ratio required for balanced charge mobility. As such, they observed an uncommon increased **PC₆₁BM** photocurrent contribution (up to 30%) for a **P3HT:PC₆₁BM** blend ratio of 1:2.

By investigating two different binary systems, Dam *et al.*²⁷ have demonstrated that the deviation from the optimal D:A ratio observed in BHJs can be directly correlated with the miscibility between the two components. Indeed, they investigated the morphology and device performance of NP-based OPV devices for two very different polymer:fullerene blends (*i.e.* **P3HT:PC₇₁BM** and a more crystalline **PSBTBT** low band-gap (LBG) polymer blended with **P₇₁CBM**, Fig. 16); the authors showed that the crystalline nature and the miscibility between (macro-)molecular components are key parameters to control the NP core and shell composition, called mesomorphology in their article. If both blends show similar core-shell NPs of comparable sizes (diameter around 24 nm) and a similar **PC₇₁BM**-rich core volume of 20% of the NPs, STXM investigations

Fig. 16 (a) Chemical structure of **PSBTBT**. (b) Schematic of small 1:1 **P3HT:PC₇₁BM** and **PSBTBT:PC₇₁BM** NPs showing the core and shell diameters and the polymer:PCBM ratio in the core and shell regions. Adapted with permission from ref. 27 (Copyright 2015 Elsevier B.V.).

allowed the authors to highlight the marked difference in core composition. Indeed, the core of the **P3HT:PC₇₁BM** NPs is considerably richer in PCBM relative to that of the **PSBTBT:PC₇₁BM** NPs (Fig. 16). Moreover, if the shell compositions are really close in both cases with a polymer fraction of around 0.7, this value for **PSBTBT:PC₇₁BM** NPs is very far from the ideal composition of **PSBTBT:PCBM** blends (reported to be 0.4 in BHJs), whereas it is only 20% higher than the ideal case for **P3HT:PCBM** (0.56 in BHJs). Consequently, the authors suggest that the region in which charge generation occurs will be different in both cases. Thus, in the **P3HT:PC₇₁BM** NPs, the charge generation is expected to be dominated by the shell region, while the opposite is true with the **PSBTBT:PC₇₁BM** NPs. However, taking into account the relative volume proportion of the core and shell in these NPs (only 20% core in the NP volume), a much lower performance OPV device can be expected from the **PSBTBT:PC₇₁BM** NPs. Indeed, if the two blends gave identical PCE values of 1.3%, the decrease in performance compared to the reference BHJ device is much greater in the **PSBTBT:PC₇₁BM** NP case. Especially a J_{sc} divided by 2.6 has been measured in **PSBTBT:PC₇₁BM** NPs compared to the same blend in BHJs, while it is divided by only 1.6 in the **P3HT:PCBM** case. These studies show that the D:A ratio can be tuned in order to optimize the shell composition of NPs.

4.2. Vertical composition through the active layer

Interestingly, in addition to the manipulation of the D:A ratio, usually performed to optimize the power conversion efficiency of OPV devices, the colloid approach also enables one to finely tune the vertical composition of thin films, thanks to a multilayer deposition approach. It has been demonstrated for vapor deposited devices that a vertical gradient in donor concentration towards the anode and acceptor concentration towards the cathode was beneficial to limit charge recombination while driving the charge to the corresponding electrodes.^{79,80} However, the vertical morphology of a film processed from solutions is difficult to control and multilayer deposition is not possible without redissolving the previous layers. In the case of

composite NPs of **F8BT:PFB** or **P3HT:PC₆₁BM**, multilayered films (up to five layers) have been prepared by varying the composition of donor:acceptor NPs for each layer to 1:0, 2:1, 1:1, 1:2 and 0:1, thus improving the V_{oc} in these devices.⁸¹ This sequential deposition strategy was also used by Gärtner *et al.*,⁵³ who prepared new device architectures, introducing variable vertical composition (Fig. 17). Device A is a reference inverted device with ITO/ZnO used as a transparent electron-collecting electrode and PEDOT:PSS/Ag as a hole-collecting electrode. Device B includes a pristine **P3HT** NP layer on the top of the active layer (*i.e.* in contact with the hole-collecting electrode). Device C includes an additional **ICBA** layer below the active layer (*i.e.* on top of the hole-collecting electrode). Finally, device D is built to bring a favorable gradient composition in **P3HT** and in **ICBA** in the active-layer and a **P3HT** NP layer on the top of the active layer. The gradient in the active-layer has been introduced by synthesizing and depositing **P3HT:ICBA** NPs with different mixing ratios. Therefore, they sequentially applied **P3HT:ICBA** (1:3) NPs and **P3HT:ICBA** (1:1) NPs atop the ITO/ZnO cathode.

In order to keep similar photon harvesting properties, and to compare only the impact of the composition gradient on the OPV device performance, they used the same amount (mass) of photo-active **P3HT**, neglecting **ICBA** absorption and thin-film interference. By combining photovoltaic and light intensity dependent photocurrent measurements, the authors concluded that the vertical composition gradient introduced in devices B and C provides enhanced percolation paths for photo-generated charge carriers to the respective electrodes. The increased FF and V_{oc} in these devices, with regards to the reference device A, combined with a FF that does not depend on the illumination intensity, support this hypothesis (see the discussion on mechanisms in Section 4.3). The PCE reaches 4.2% for both devices B and C, compared to a PCE of only 3.7% in device A. Device D exhibits unfortunately a lower PCE of only 3.9%, probably because of a thinner active layer, as confirmed by a significantly lower J_{sc} . However, no significant dependence of the FF on the illumination intensity between $I = 250 \text{ W m}^{-2}$

Fig. 17 Device architectures: (a) reference device comprising an ITO/ZnO bottom cathode and a PEDOT:PSS/Ag top anode as well as a nanoparticle **P3HT:ICBA** absorber layer. (b) Neat **P3HT** nanoparticles were introduced between the absorber layer and the PEDOT:PSS layer. The nanoparticle **P3HT** top layer is not closed with its thickness of 15 nm representing the average layer thickness. The thickness of the entire absorber layer was reduced to match the overall amount of **P3HT** in configuration A. (c) A 15 nm nanoparticle **P3HT** and a 20 nm **ICBA** interlayer were introduced. The overall amount of **P3HT** and **ICBA** approximately matches the reference device. (d) The vertical composition of the **P3HT:ICBA** layer was varied by subsequent deposition of nanoparticles with different mixing ratios ((1:3), (1:1), and neat **P3HT**). Adapted with permission from ref. 53 (Copyright 2016 The Royal Society of Chemistry).

and $I = 1000 \text{ W m}^{-2}$ has been observed, highlighting again the probable enhanced percolation pathways for photo-generated charge carriers.

Such a multilayer approach paves the way towards tandem device development, which has already been demonstrated to be a promising approach for effectively managing the absorption properties of such OPV devices.⁸²

4.3. Limiting mechanisms in the particular case of OPV devices made from NP dispersions

The most studied blend for OPV cells is based on an electron-donor polymer (P3HT) and an electron-acceptor small molecule (PC₆₁BM).⁵⁸ This reference blend has been therefore widely studied for NP solar cells, as we have seen throughout this manuscript. This blend is therefore a suitable reference for attempting to analyze the main factors limiting the efficiencies of OPV devices made from dispersions, in comparison with devices made from the same materials in solution. Two major mechanisms can hinder the OPV cell PCE. The first one is the free charge-carrier generation, which necessitates exciton dissociation, and the second one is free charge extraction. For both mechanisms, the specificity of NP active layers can be questioned. Further, separate P3HT and PC₆₁BM NPs that are blended to form the active layer and intimate blends of P3HT and PC₆₁BM in the same NP forming the active layer (composite NPs) can intuitively have different behaviors in terms of charge generation and charge extraction.

In 2018, Al-Mudhaffer *et al.*⁸³ used core-shell P3HT:PC₆₁BM composite (1:1) NPs, prepared by miniemulsion, as the active layer of a direct structure solar cell (ITO/PEDOT-PSS/active layer/Ca/Al) and studied in detail the light-absorption and charge-extraction properties of their solar cells. They compare their NP solar cells with conventional bulk heterojunction (BHJ) solar cells ((P3HT:PC₆₁BM) (1:0.8)) as a reference cell. On the one hand, a careful analysis of the optical properties of the cells led the authors to rule out plasmonic effects or light scattering by the nanoparticles as important mechanisms to explain different light absorption behavior. On the other hand, the spectral response of the OPV cells together with extraction of the different parameters to calculate the internal quantum efficiency led them to conclude that the main limiting parameter in their NP solar cells is the low exciton dissociation efficiency in that type of device, probably originating from the core-shell donor-acceptor morphologies in the active layer (Fig. 18).

This conclusion is in contradiction with other reports on different systems. For instance, Gärtner *et al.*⁷⁸ elaborated inverted solar cells (ITO/ZnO/active layer/MoO₃/Al) based on composite NPs of P3HT and ICBA made by nanoprecipitation. They carefully investigated the photovoltaic parameters and the film morphology evolution as a function of thermal annealing treatments. They obtained, after an optimal annealing step, an efficiency comparable to BHJ solar cells elaborated from solution with similar architecture devices with, in particular, a high short-circuit current density (J_{sc}) and a high open-circuit voltage (V_{oc}) but with negligible variations in the morphology of

Fig. 18 Schematic illustration of the different mechanisms leading to power conversion in BHJ and NP P3HT:PC₆₁BM solar cells. The exciton dissociation is a marked difference between BHJ and NP devices. Adapted with permission from ref. 83 (Copyright 2018 Elsevier B.V.).

the film and in the crystallinity of the NPs during the thermal annealing. Their conclusion was that thermal annealing reduces the recombination of the free-charge carriers in NP devices but did not impact the free-charge generation, which was already efficient, even in non-annealed devices. Indeed, in the case of nanoprecipitation, composite NPs are uniform with segregated domains smaller than 10 nm. Consequently, the as deposited NP film morphology already resembles the ideal BHJ morphology with nanophase separation. With the same electron-donor polymer but using a non-fullerene acceptor (NFA), namely *o*-IDTBR (Fig. 10), Xie *et al.*⁴⁹ elaborated inverted solar cells (ITO/ZnO/active layer/MoO_x/Ag) with a composite NP active layer. Comparing NP devices with BHJ devices made of the same system, they extracted explicitly the free-charge carrier generation rate, which is equivalent in NP and BHJ solar cells. It seems therefore that using carefully elaborated NPs (and especially composite NPs) and optimized devices, the free-charge carrier generation *via* exciton dissociation is not the limiting factor in NP solar cells.

Once the free-charges are generated, the charge extraction may be problematic in NP solar cells. Different methods can be used to anticipate or to directly measure the charge-extraction efficiency. One of them is to measure the charge-carrier mobility.

Charge transport properties are a key concern in organic semiconducting materials for electronic applications and in particular for OPVs.⁸⁴ The hole and electron mobilities should be high enough to use thick active layers, but they should also be well balanced to avoid internal electric field screening by space-charge zones. It is therefore crucial to check that charge transport occurs through a thin film obtained from NP dispersion deposition. Different devices can be used to probe the mobility, either along the substrate plane or in the out-of-plane direction. For example, Organic Field Effect Transistor (OFET) devices provide mobility values in the substrate plane,⁸⁵ while Time Of Flight (TOF)⁸⁶ devices or Space Charge Limited Current (SCLC)⁸⁷ diodes allow one to estimate mobilities in a direction perpendicular to the electrodes (out-of-plane direction), which is the preferential direction of charge transport in multilayer OPV devices. However, one has to be careful when comparing mobility values extracted from different devices, using various architectures and elaborated in disparate conditions. For instance, OFET and TOF devices do not involve at all the same charge carrier

density, which is much higher in OFET devices, nor the same active-layer thickness, which is much higher in TOF experiments. Such a difference usually results in a significantly higher OFET mobility value, except in the case of a very pronounced charge-transport anisotropy with a highly favored out-of-plane mobility for structural solid-state reasons.

Bag *et al.*⁶¹ estimated the hole transport mobilities in **P3HT** NP films using TOF measurements. They found hole mobilities on the same order of magnitude as for **P3HT** pristine thin films but the TOF measurements showed very dispersive characteristics. Decreasing the surfactant concentration led to less dispersive hole transport. A high surfactant concentration hindered the close packing of the NPs and increased the dispersive character of the hole transport in NP films. This behavior was further observed and explained by Han *et al.*,⁸⁸ who analyzed their TOF measurements in the frame of a conventional set of diffusion and drift equations. The authors showed that the presence of surfactants in **P3HT** NP films increased the trap concentration as well as the trapping rate for charge carriers (in agreement with the observed dispersive hole transport). They get one step further in their analysis, showing that the detrapping rate in the presence of surfactants was really high, meaning that the surfactant trap state is associated with shallow trapping energy levels and low activation energy barriers so that the trapped holes can be easily detrapped to contribute to the hole current. The hole current is therefore more dispersive in the presence of surfactants and one order of magnitude lower than for surfactant-free NP films or drop-cast **P3HT** films, but the hole transport is not completely hindered in surfactant **P3HT** NP films. Another important conclusion of this study was that for drop-cast **P3HT** films or **P3HT** NPs where the NPs contained or not a high concentration of surfactants, the energetic or positional disorder was in the same range. All the conclusions drawn here are for TOF studies in **P3HT** NP films only and the situation can be very different in the active layer of solar cells.

A few publications are devoted to the comparison of the charge carrier transport properties measured by TOF of **P3HT:PC₆₁BM** thin films made either from separate NPs or composite NPs.^{68,89} Gehan *et al.* showed the existence of conductive pathways for holes through the bulk for separate as for composite NP films but with clearly more short pathways with low resistance for separate NP films. The TOF hole mobility was slightly lower in separate **P3HT:PC₆₁BM** (1:1) NP films ($8 \times 10^{-5} \text{ cm}^2 (\text{V s})^{-1}$) than in pure **P3HT** NP films ($2 \times 10^{-4} \text{ cm}^2 (\text{V s})^{-1}$) with in both cases a weak dependence with the electric field. In composite NP films, even though the hole mobility at low electric field was comparable to the **P3HT** NP film one, a marked decrease of the hole mobility was observed at high electric field. Such a behavior is in agreement with an increase of the positional disorder in composite NP films.⁹⁰ The very same conclusion was made by Han *et al.*⁸⁹ They get even one step further, connecting the charge trap-site density to the charge transport pathway lengths. In composite NP films, each NP contains electron-transporting and hole-transporting materials, leading to continuous charge transport

pathways with shorter charge hopping distances. In separate NP films, longer and more tortuous pathways for charge transport are anticipated. The charge-carrier trap-site density depends closely on the surfactant presence in the prepared NPs, highlighting the importance of surfactant removal strategies to obtain good charge-transport properties in NP films. In these two publications,^{68,89} a strong emphasis was put on device engineering for efficient photovoltaic devices based on NPs. In particular, the authors insisted on the influence of interfacial layers (electron transporting layers or ETLs and/or hole transporting layers or HTLs) to promote charge extraction. The authors highlighted the beneficial use of an ETL (a **PC₆₁BM** layer) on top of the active layer and before the electron-collecting electrode deposition in a direct structure. This is also true for inverted structures and charge dynamics analysis on OPV cells is only valid if it is performed on optimized solar cells. A first rough estimate of the charge-carrier dynamics consists of studying the photovoltaic parameter variation as a function of light intensity. Gärtner *et al.*⁷⁸ showed that for **P3HT:ICBA** NP solar cells in an inverted structure (ITO/ZnO/active layer/MoO₃/Al), J_{sc} in thermally annealed optimized devices varied almost linearly with the light intensity. This behavior indicates the predominance of monomolecular charge-carrier recombination at high electric field (short-circuit conditions) as expected in efficient OPV systems where bimolecular recombination does not hinder charge-extraction.⁹¹ For a very similar system, Gärtner *et al.*⁵³ observed a strong drop of the FF when the light intensity increases, showing that when the electric field decreases, the bimolecular recombination mechanism became more important. Further, Gärtner *et al.* changed the active-layer configuration to vary the percolation pathways toward the electrodes and favor charge extraction. They indeed showed that this strategy lowered the bimolecular recombination at low electric-field and ultimately improved the power conversion efficiency. The only way to efficiently study the charge-carrier dynamics is nevertheless a combination of transient photovoltage (TPV) and charge extraction (CE) as performed by Xie *et al.*⁴⁹ on efficient OPV NP blends. Optimizing the NP elaboration as well as the device fabrication, they obtained a more than 5% efficiency with a composite NP active layer with **P3HT** and **o-IDTBR**. The measured recombination order (R) in the optimized NPs system is higher than two ($R = 2.89$) indicating the remaining presence of charge-carrier trap sites. However, it approaches the R measured for optimized (**P3HT:o-IDTBR**) BHJ solar-cells ($R = 2.1$) showing that efficient organic photovoltaic cells that are not limited by charge transport and extraction can be processed from NPs. This conclusion is confirmed by the high PCEs measured by the same authors on different systems and described below.

4.4. Device optimization through chemical selection

The recent progress observed in BHJ OPVs is mainly due to the development of device architectures (interlayers, electrodes, coating process, *etc.*) and photoactive materials. As seen in previous sections, due to their commercial availability and moderate costs, **P3HT** and **PC₆₁BM** continue to be considered as reference systems for in-depth physico-chemical and physical studies on the structural and electrical properties of OPV active layers.^{58,96}

However, their intrinsic optical and electronic properties limit the performance of OPV solar cells. One easy and known strategy to achieve higher efficiencies is to replace PC_{61}BM with a fullerene bisadduct called **ICBA**. The **ICBA** derivative has indeed a LUMO level about 0.1–0.2 eV higher than PC_{61}BM , which improves V_{oc} , and is also more soluble in organic solvents.⁹⁷ Using this **P3HT:ICBA** binary system, Ulum *et al.*²⁸ early described the elaboration of core-shell NPs with an **ICBA**-rich core and a **P3HT**-rich shell. Interestingly, as seen previously, **ICBA** being more miscible in **P3HT** than PC_{61}BM , at all weight fractions they showed that a standard thermal annealing step led to a more blended morphology. Indeed, upon thermal annealing, the core-shell structure is lost, the particles merge together and the **ICBA** migrates from the core to the shell (Fig. 19). Further STXM observations support this scenario. This blended morphology provides enhanced charge carrier pathways and results in an improved FF after thermal annealing (around 55% against 35% for unannealed thin films). They thus recorded a best PCE of approximately 2.5% with an expected improved V_{oc} of almost 800 mV. Later, using the same blend and optimizing both the device structure and active layer deposition process, a few teams reported PCEs more in line with the reference values obtained for BHJs, in the range of 4 to 4.5%.^{42,53,78} It should be noticed that in 2016 Sankaran *et al.*⁶⁰ reported 1.1 cm^2 active area solar cells deposited by doctor blading from the **P3HT:ICBA** binary system with a PCE of 3.4%, thereby showing the benefits of this approach in terms of process (see Table 2).

Although progress has been made through the use of this **ICBA** fullerene derivative, the PCEs remain far from the standards nowadays measured in conventional BHJs. Indeed, the OPV field experienced a very recent and rapid development of photoactive materials with properties increasingly more appropriate for photon harvesting and charge carrier transport, such as low band-gap (LBG) polymers^{5,98} and non-fullerene acceptors (NFA).⁹⁹ However, these materials, particularly the LBG polymers, generally have a much lower solubility than the reference **P3HT**.^{6,100} Obviously, this makes their dissolution tricky in low-boiling organic solvents. Consequently, NP synthesis and stable dispersion elaboration are challenging. This probably

explains why very few studies have been done on LBG polymer NPs.

However, although exhibiting very low PCEs, it could be noticed that very early on, many groups studied other conjugated polymers, such as the **PFB** fluorene derivative previously discussed.^{18,59,70}

Another extensively studied building-block for OPV application is diketopyrrolopyrrole (**DPP**). It exhibits indeed extraordinary charge absorption and transport properties associated with good solubility due to the presence of two alkyl side-chains.¹⁰¹ In this regard, it appears to be a scaffold of choice for preparing NP dispersions. Therefore, several studies have used **DPP** in combination with different comonomers to prepare NP based OPV devices (see the **PDPP5T** and **PDPP-TNT** structures in Fig. 20 and 14, respectively).^{75,93} However, the best PCE reported recently by Xie *et al.*⁹⁵ is limited to 3.5%. Although promising, this work also highlights a limitation commonly encountered in NP-based devices, non-geminate recombination due to lower charge carrier mobilities and higher densities of traps (see Section 4.3 on limiting mechanisms).

Recently, D'Olieslaeger *et al.*¹⁵ used another well-known building-block in OPVs, benzodithiophene (**BDT**).¹⁰² They described the fabrication of organic solar cells from mixed NPs elaborated by miniemulsion, using a mixture of **PBDTTPD**, a moderate band-gap **BDT**-based polymer (Fig. 20), and PC_{71}BM , which reached best PCEs of 3.8% after a thermal annealing step. As already demonstrated on the reference **P3HT:PC₆₁BM** system, this thermal annealing step, whose characteristics (time and temperature) must be adapted to each binary blend, has the effect of melting particles into a continuous interconnected film with enhanced continuous pathways for holes and electrons.

As seen in all the previously discussed examples, the NP-based BHJ approach is highly appealing but still suffers from a number of limitations: (i) in the miniemulsion case, the presence of surfactant and the predominantly core-shell nature of the synthesized NPs limit the charge carrier transport and extraction; and (ii) in the nanoprecipitation case, the control of the NP size is difficult and the resulting dispersions lack stability.

Fig. 19 Schematic model of NP evolution during elaboration and thermal treatment. During NP formation, **P3HT** tends to migrate toward the shell due to its lower surface energy. A core-shell NP is obtained with a core containing 41% **ICBA** and a shell containing only 23% **ICBA**. After drying of the NPs (110 °C for 4 min), the **ICBA** shell composition increases to 34%, while the core composition remains the same. Finally, during thermal annealing at 150 °C for 15 min, **ICBA** continues to migrate toward the surface of the particles, resulting in homogeneous NPs with an average **ICBA** composition of 32%. Part of the **ICBA** is also lost from the NPs during annealing and small crystallites can be observed outside the NPs. Reprinted with permission from ref. 28 (Copyright 2018 Elsevier B.V.).

Fig. 20 Chemical structures of diketopyrrolopyrrole (DPP) and PDPP5T, and of benzodithiophene (BDT) and PBDTTPD.

In this context, Xie *et al.*⁴⁹ recently reported a very promising and innovative NP synthesis approach called the surfactant assisted nanoprecipitation technique as described in Section 2.2. This concept based on a non-ionic surfactant Pluronic F127 with temperature sensitive critical micelle concentration (cmc) was demonstrated to stabilize NPs. After preparation, surfactant stripping from the NPs was facilitated by its increased solubility at low temperature. This highly versatile approach enables the synthesis of high purity light-harvesting NPs by minimizing the amount of residual surfactant in the aqueous system. Consequently, in NP films with low surfactant amounts, electron donor polymers are able to reorganize and exhibit higher crystallinities and charge-carrier mobilities. In addition, the versatility of this approach is highlighted by the authors, who successfully obtained several composite polymer:NFA NPs. Thus, a champion PCE of 5.23% with a high FF of 65% was achieved for **P3HT:o-IDTBR** NP solar cells, being comparable to the devices processed from halogenated solvents. Moreover, NP-based devices using the low-bandgap polymer **PBQ-QF** (Fig. 10) further boosted the record PCE of water/alcohol-processed OPVs up to 7.5%. However, it is important to notice that this approach requires the use of organic semiconductor materials that are soluble in THF, which is not the case for most of them. Nevertheless, by overcoming the charge transport and recombination limits usually experienced in NP-based devices with traditional ionic surfactants, this approach paves the way towards a more systematic use of water-based dispersions in the OPV field.

5. Conclusion

In this article, we reviewed the NP dispersion strategy to elaborate the photoactive layer of bulk heterojunction (BHJ) organic solar cells. The main aim of using NPs in that case is to avoid the use of toxic solvents while still controlling the morphology at a nanometer scale.

Miniemulsion and nanoprecipitation are the main strategies to produce single or composite organic semiconducting NPs (containing both the electron-donor and the electron-acceptor material). It has been shown that the internal morphology of the NPs depends greatly on the used technique. While the miniemulsion technique seems more versatile and produces stable NP dispersions, it leads more frequently to composite core-shell NPs. Moreover, removal of the surfactant is necessary to improve the active layer homogeneity and the OPV efficiency. In the case of nanoprecipitation, the two semiconducting materials are better mixed with smaller domains inside the NP, their morphology being closer to the one of the active layers obtained by solvent casting. However, the NPs are less stable due to the absence of surfactant. To solve this problem, surfactant assisted nanoprecipitation was recently developed and appeared as a very promising route leading to a record PCE of 7.3%.⁴⁹ Further, the morphology of the active layer obtained by the assembly of the synthesized NPs has also been discussed thoroughly as well as its influence on the charge-carrier dynamics. Specifically, the exciton dissociation efficiency and the charge-carrier transport and collection properties have been described in light of the specific photoactive-layer morphologies obtained from NP inks. Finally, different photovoltaic parameters including the Power Conversion Efficiency (PCE) of NP devices have been analyzed.

Research on OPV device elaboration from NP dispersions has made significant progress in the last decade and the PCE values reached by this approach are nowadays compatible with industrial criteria. Moreover, using NPs for the elaboration of the active layer of BHJ solar cells appeared to be an efficient way to finely tune the active-layer morphology. Further, it opens the way to interesting concepts like controlled vertical composition gradients in BHJ solar cells, which may lead to real breakthroughs in terms of efficiency. However, a lot of effort is still needed to get closer to the performance standards of solution processed organic solar cells. In particular, we believe that

customized materials can be developed in order to better adapt the physico-chemical properties of organic semiconductors to the constraints of NP elaboration. In particular, the use of polar side chains would help to make such semiconducting materials more soluble and simultaneously organic semiconductor-based nanoparticles more stable in alcohol or water. Interestingly, driven by other applications like thermoelectricity, water photocatalysis, electrochemical energy storage or bioelectronics,¹⁰³ such conjugated materials are currently undergoing significant development.^{104–106}

We are therefore convinced that the NP approach is a major step not only toward the industrialization of organic photovoltaics, but also towards the use of these semiconducting polymer materials in many other applications, as illustrated recently by Kosco *et al.*¹⁰⁷ in photocatalytic hydrogen production.
