Advances in materials and devices for mimicking sensory adaptation

Zihan He,^{ab} Dekai Ye,^a Liyao Liu,^a Chong-an Di ^{*a} and Daoben Zhu ^{*a}

Adaptive devices, which aim to adjust electrical behaviors autonomously to external stimuli, are considered to be attractive candidates for next-generation artificial perception systems. Compared with typical electronic devices with stable signal output, adaptive devices possess unique features in exhibiting dynamic fitness to varying environments. To meet this requirement, increasing efforts have been made focusing on developing new materials, functional interfaces and novel device geometry for sensory perception applications. In this review, we summarize the recent advances in materials and devices for mimicking sensory adaptation. Keeping this in mind, we first introduce the fundamentals of biological sensory adaptation. Thereafter, the recent progress in mimicking sensory adaptation, such as tactile and visual adaptive systems, is overviewed. Moreover, we suggest five strategies to construct adaptive devices. Finally, challenges and perspectives are proposed to highlight the directions that deserve focused attention in this flourishing field.

1. Introduction

Driven by the rapid development of artificial intelligence, smart devices that can mimic and even exceed the perception capabilities of human beings have attracted increasing attention.^{1–3} So far, there are two kinds of artificial perception-related devices being widely studied. The first category is used to detect target

biological substances or physiological signals, which serve as electronic sensors for signal transduction.^{4–9} Another category of devices can simulate biological functions.^{10–20} The existing efforts have been focused on synaptic devices and have led to different kinds of neuromorphic elements. Although these devices can combine together to enable artificial perception elements, the integrated devices cannot exhibit adaptation abilities like those in biological systems. Under this circumstance, it is highly desirable to develop adaptive devices – which exhibit dynamic fitness to environmental conditions – that can automatically adjust their response to varying stimuli.

“Survival of the fittest” is a basic biological concept of natural adaptation. All living systems, from a single cell to multicellular organisms and populations of interacting

species,²¹ have the ability to adapt to changes in their environments.^{22,23} Humans have also evolved over time to develop the five exquisite sensory systems, which enable us to see, hear, taste, smell and touch for the vibrant perception of and complex interactions with the world. Every biological sensory system begins with a receptor that responds to physical stimuli to initiate a sensation.²⁴ All sensory receptors have a form of adaptation to constantly detect changes in environments, which enables weak sensory inputs to be amplified and protected from noise while preventing strong inputs from saturating neural responses.²⁵

Along with the booming development of artificial perception systems,^{1,26–29} adaptive devices have attracted significant interest for human–machine interfaces, physiological simulation, and prosthetic applications.^{30–32} The construction of adaptive devices typically requires devices in which information processing capability is merged with sensing ability to external stimuli. Historically, complementary metal–oxide–semiconductor (CMOS) circuits have played an important role in mimicking sensory adaptation since the 1990s.^{33,34} These silicon-based circuits often comprise several tens to hundreds of transistors and capacitors, leading to complicated logic designs. Recently,

organic semiconductors (OSCs) have attracted increasing interest owing to their intrinsic features of good flexibility, solution processability, biocompatibility, *etc.*³⁵ Based on these unique properties, a series of OSC-based devices, including organic electrochemical transistors (OECTs),³⁶ tactile adaptation elements,^{37–43} organic adaptive transistors (OATs),³⁰ and organic active adaptation transistors (OAATs),⁴⁴ have been developed (Fig. 1). As a most recent example, our group developed an OAAT that possesses active visual adaptation ability to changeable light irradiation like human beings.⁴⁴ These achievements boost the rapid development of this emerging area.

Along with the aforementioned developments, several strategies centring on functional materials,^{45,46} operating mechanisms^{32,47,48} and device architectures³⁰ have been proposed to develop adaptive devices. However, there is no review focusing on the materials and device engineering of sensory adaptation. Here, we provide the recent progress in and perspective for adaptive electronics. We start with a brief introduction to sensory adaptation. Second, representative advances of sensory adaptation-inspired devices, including tactile-adaptive systems and visual-adaptive systems, are reviewed. We then present strategies to construct state-of-the-art adaptive devices. Finally, we suggest directions to stimulate more research interests in this intriguing area.

Liyao Liu

Liyao Liu received her PhD degree from the Institute of Chemistry, The Chinese Academy of Sciences (ICCAS), in 2019, and joined the ICCAS as a technician. Her research interests are focussed on organic thermoelectric materials and devices.

2. Fundamentals of sensory adaptation

We first introduce the biological adaptation behaviours to provide a fundamental understanding of adaptive devices. Biological sensory systems adjust their input–output relation according to external stimuli.^{23,49} A common phenomenon is a decrease in the gain of response to a continuous input; this is called sensory adaptation.⁵⁰ When a stimulus is applied to sensory receptors and its final intensity is maintained at a stable level, the receptor responds with a series of action potentials, the frequency of which is initially high and then decreases. For humans, there are five categories of receptors (photoreceptors, olfactory receptors, mechanoreceptors,

gustatory receptors and hair cells) responsible for sensory adaptation. For instance, mechanoreceptors exhibit different adaptive characteristics to external stimuli. Slow adapting (SA) receptors are sensitive to static pressure or touch and can produce a sustained signal in response to sustained stimuli. In contrast, fast adapting (FA) receptors can detect dynamic vibrations or sliding only at the beginning or end moments of the stimulation.^{39,51} As another example, photoreceptors adapt to background illumination, in order to amplify weak sensory inputs and prevent strong inputs from saturating.²⁵ As a result, light adaptation allows eyes to quickly adapt to strong light,^{52,53} while dark adaptation enables the recovery of sensitivity in the dark.

To date, two network topologies have been proposed to understand the mechanism of sensory adaptation.^{54–56} The first model indicates that adaptation comes from a negative feedback loop (NFL), and such adaptation is based on the integral of the difference between the desired and achieved responses. Based on this network motif, previous studies of adaptation devices are focused on designing error-correction-based feedback circuits, and have led to a wide range of

applications in brightness and exposure control. The second class of models assumes that adaptation results from an incoherent feedforward loop (IFFL). This model posits that adaptation results from two complementary processes of excitation and inhibition that together regulate a response regulator. In fact, both NFL and IFFL models are indispensable in biological systems to realize dynamic adaptation.

Several key parameters are proposed to evaluate the adaptation abilities. Sensitivity is defined as the height of output response relative to the initial steady-state value, which reflects the largest transient relative change of the output divided by the relative change of the input.⁵⁷ The decay constant (τ) is another parameter because it determines the timescales of the adaptation process, and the decay in firing rate can be described by a power-law relationship. T is the time at which the quantity is reduced to $1/e$ times of its initial value. Notably, the rate of adaptation differs widely in different sensory receptors. For example, four distinct types of mechanosensitive response can be classified as rapidly adapting ($\sim 3\text{--}6$ ms), intermediately adapting ($\sim 15\text{--}30$ ms), slowly adapting ($\sim 200\text{--}300$ ms) and ultra-slowly adapting modes

(~ 1000 ms).⁵⁸ In photoreceptors, brief timescales reveal a rapid decay (~ 30 ms) whereas a more prolonged decay constant (2–60 s) reveals a slower process.⁵⁹ As adaptation allows sensory systems with an autonomic response to varying environments, it is vital to evaluate the response change relative to the external stimuli. We defined the active adaptation index (AAI) as the response change in the adaptation process relative to the increase of orders of luminance magnitude.⁴⁴ For our OAAT, the AAI reaches its maximum value of 12.4 at the luminance of 10^5 – 10^6 cd m⁻². The performance is consistent with that estimated from human beings.

3. Progress in sensory adaptation devices

To develop adaptive devices, several aspects should be taken into consideration. Take the existing organic adaptive transistors for example.³⁰ Both stable and high mobility charge transport are required in the conductive channel, whereas charge trapping is indispensable in the dielectric layer. As a result, organic semiconductors with high mobility and fine-tuned energy levels relative to the dielectric layer are of vital importance. As for tactile-adaptation elements,^{37,38,40–42}

applying external forces on the devices leads to variation in the signal output. Thus, several soft polymers with structural elasticity, chemical stability, piezoelectricity, *etc.* may have great potential for constructing adaptive devices. For mimicking visual adaptation, such as reported OAATs,⁴⁴ prominent charge transport and efficient photocarrier generation are required in the photoresponsive active layer. As a result, the development of multifunctional materials and the design of unique device geometry are of significant importance. Fig. 2 displays the molecular structures of the mentioned materials in this review, including OSCs,^{30,44} conductive polymers,³⁶ soft materials,^{37,38,40,43} *etc.* Based on these materials, we summarize the recent progress in the development of tactile and visual adaptive systems.

3.1. Tactile-adaptive system

To construct artificial tactile-adaptive systems, it is important to understand the key factors that affect the adaptation properties. As mentioned above, tactile adaptation is enabled by the combined efforts of various mechanoreceptors. Typically, there are four mechanoreceptors in the human skin that adapt quickly and slowly: Meissner corpuscle (MC), Merkel disk (MD), Ruffini cylinder (RC) and Pacinian corpuscle (PC).⁶⁰

Fig. 2 Molecular structures of materials discussed in this review.

While MDs and RCs show the characteristics of SA, PCs and MCs show the characteristics of FA (Fig. 3a). Basically, adaptation is enabled by ion channel-gating in biological systems.^{30,58} When a sustained stimulus is applied, the ion channel is activated and then gradually inactivated, with recovery after the removal of the stimulus (Fig. 3b). As a result, the response of mechanoreceptors gradually decreased and was then maintained at a stable level during the adaptation process (Fig. 3c). In order to mimic the tactile-adaptation characteristics, it is essential to develop an element that can imitate both SA and FA behaviors as human receptors.

Han *et al.* developed a self-powered artificial mechanoreceptor by spatially integrating a piezoelectric film and an ion channel system into one device (Fig. 3d).⁴¹ The device is fabricated with an electrode (Al/C), an electrolyte (polyaniline (PANI) solution), a pore membrane (MB) and a piezoelectric film (Au/PVDF). When the device is pressed and released, ion movement in the PANI is observed through the

polycarbonate track-etched MB, thus mimicking SA signals, while the signal generated from the connection between the upper part of the Au/PVDF and the Al/C exhibits the characteristics of FA. Both the functions of FA and SA can be accomplished simultaneously, and typical adaptation signals in the rest and exercise states can be observed under repeated stimuli (Fig. 3e). Recently, Arias *et al.* demonstrated a single-mode mechanoreceptor based on a potentiometric–triboelectric hybridized configuration (Fig. 3f and g) that exhibits self-adapting behaviours.⁴³ The device can be regulated from slow adapting to medium adapting and fast adapting mode according to the external stimuli (Fig. 3h). In addition, such a device can also adapt to diverse mechanical characteristics, including magnitude, frequency, duration, applying and releasing speed, for resolving complex stimuli.

In biological sensory systems, tactile stimuli are converted into action potentials and then transmitted *via* afferent nerves. In previous reports, pressure information can be converted into

voltage pulses using ring oscillators.^{61,62} Recently, an artificial neural tactile sensing system that can mimic SA and FA mechanoreceptors, as well as generate sensory neuron-like signals, was demonstrated.⁴⁷ The tactile skin (T-skin) films were fabricated by incorporating FA-mimicking BaTiO₃ nanoparticles and SA-mimicking reduced graphene oxide (rGO) sheets in an elastic polymer matrix, enabling a sensitive response to static pressure and vibration simultaneously (Fig. 4a). The SA sensors produce piezoresistive responses under static pressure (0.1–100 kPa), which matches well with the typical human perception range (Fig. 4b).⁶³ And, even high-frequency vibrations of 1000 Hz that exceed the human vibration detection range can be achieved in FA sensors (Fig. 4c).⁶⁴ Furthermore, the SA- and FA-type neural signal patterns similar to real tactile nerve signals can be generated using an artificial mechanoreceptor neural (AMN) board. Such SA or FA neural simulator signals can be fully transmitted in real nerves or can activate the hindlimb muscles (Fig. 4d and e). Recently, we developed an OAT with fine-tuned adaptation functionality.³⁰ Interestingly, the adaption speed can be modulated from ultraslow to fast adaptation through dielectric engineering. Notably, the FA-OAT has been utilized to construct an artificial

tactile circuit. The effective detection of pressure onset and offset in this circuit was stimulated successfully based on the FA-on and FA-off device, respectively.

3.2. Visual-adaptive system

Studies from neuroscience and cognitive psychology have revealed that more than 80% of the information from the outside world reaches the brain through vision.⁶⁵ The environmental light intensity ranges over ten orders of magnitude in our daily life, whereas the firing rate of optical nerve fibres spans less than two.^{66,67} The existing gap between the light stimulus and processable signal is filled by the visual adaptive system, where an active shift of visual threshold and sensitivity occurs according to the luminance backgrounds. Notably, this biological functionality is achieved *via* a coupled physiological mechanism, that is, pupil constriction, photo-pigment depletion, and receptor depression, to enable both sensitive response to dim lights and automatic depression to high brightness stimuli. To meet these requirements, photoadaptive devices with fine-tuned sensitivity are in demand. In modern electronics, self-adaptive optical regulation systems with automatic brightness and exposure control functionality have been

Fig. 5 Examples for mimicking visual-adaptive systems. applied, but they cannot match the adaptation behaviors in bio-systems. Recently, numerous efforts have been made to achieve this goal. An environment-adaptable optoelectronic circuit array that emulates biological visual functionalities can be used to achieve bionic visual perception (Fig. 5a).³¹ The function of light adaptation was emulated by integrating a CdSe photosensor, an IGZO load transistor and a metal oxide synaptic transistor. In this device, the visual threshold to environmental light intensities can be controlled by the load gate bias (V_L), where the visual image under bright light can be perceived by enlarging the V_L , while weak light can be distinguished by decreasing the V_L . Additionally, a 3 × 3-pixel array of neuromorphic circuits was fabricated to demonstrate the environment-adaptable pattern recognition features (Fig. 5b).

As the intensity of light condition decreased, a high contrast 'H' image could be clearly discriminated because of lowering the load gate voltage (Fig. 5c and d). This system proves the feasibility of using adaptable devices in complicated environments.

Kim *et al.* developed a neuromorphic phototransistor based on the hybrid structure of CsPb(Br_{1-x}I_x)₃ perovskite and MoS₂ that exhibits selective red-adaptation (Fig. 5e).³² A gradually decreased I_{DS} was observed under red light illumination ($\lambda = 638$ nm); here, the underlying mechanism is the halide phase segregation of the mixed halide perovskite, leading to iodide- and bromide-rich domains. As the energy of the red light was lower than that of the PL spectra for the bromide-rich domain, that is, energy band gap widening by the bromide-rich domain, significant photocurrent degradation was observed

over time (Fig. 5f and g). This photosensory-adaptation behavior can be potentially applied to artificial intelligence and may pave a new way for color-selective adaptive elements. Having mentioned that, a breakthrough in mimicking visual adaptation is the creation of an OAAT.⁴⁴ This device exhibits light intensity-dependent active photoadaptation, for light stimuli ranging over six orders of magnitude. This photoadaptation element is capable of mimicking dynamic visual adaptation behaviors. We will have a comprehensive description of this work in Section 4.4.

4. Strategies to construct sensory adaptation devices

Different perception conditions require varied categories of adaptive devices. However, all systems have much in common in terms of output signals, which generally exhibit dynamic responses under sustained stimuli. An ideal adaptive device should decline dynamically and controllably in response to sustained stimuli while maintaining long-term stability to repeated stimulations. Based on this nature, there are several strategies for constructing adaptive devices. Herein, we summarize five concepts for the design of adaptive devices.

4.1. Enabling adaptation by manipulating the charge trapping–detrapping process

Charge trapping typically leads to unfavourable current decay and plays a negative role in determining stability in an

electronic device. However, controllable decay represents an important feature for most adaptive devices. Consequently, fine-tuned charge trapping and detrapping processes can principally serve as a strategy to enable adaptation. Keeping this in mind, a recent work utilizing the charge trapping mechanism has been demonstrated based on a field-effect transistor (FET).⁴⁵ The device is fabricated with a MoS₂ semiconducting channel, hexagonal boron nitride (h-BN) tunnelling insulator, and graphene (Gr) floating gate (Fig. 6a). The underlying mechanism for the adaptation feature is ascribed to the occurrence of trapping events at the MoS₂/h-BN interface,⁶⁸ where the trapped electrons block the electric field from the gate, resulting in a smaller effective gate voltage. The output current degrades over time when the gate bias changes from 20 to 50 V (Fig. 6b), and such decreasing adaptation behaviour can also be observed under different amplitudes (Fig. 6c).

Another work based on the charge trapping–detrapping mechanism has been carried out based on a mixed-dimensional heterojunction transistor.⁴⁶ The device is fabricated with a gated-modulated 0D-CsPbBr₃-quantum-dots/2D-MoS₂ heterostructure (Fig. 6d), and 2D-MoS₂ was chosen as the bottom channel of the vertical heterojunction due to its controllable charge transport properties.^{69,70} The charge trapping–detrapping behavior is observed in the space charge region of the heterojunction (SCRH), resulting in the clear decay of I_{DS} , which serves as the basic condition to mimic sensory adaptation (Fig. 6e and f).⁷¹ Upon the onset of positive

V_{GS} , a significant peak current is generated in a short time as a result of the rapid and effective accumulation of electrons in the conductive channel. Subsequently, the time-dependent electron-trapping phenomenon occurs in the SCRH formed between MoS_2 and quantum-dots (QDs), leading to a clear decrease of I_{DS} .^{72,73} This process corresponds to the typical adaptation behavior in biological systems. And, a rapid electron-detraping phenomenon would result in an immediate recovery of the device performance after the removal of external stimuli, thus promoting the entire adaptation process. In addition, a series of adaptive behaviors, such as accuracy, sensitivity, inactivation and desensitization, have been successfully stimulated, implying promising applications in artificial intelligence and bionic robots.

4.2. Optimization of device geometry for controllable adaptation

As mentioned above, an adaptive device requires short-term decay in output current and prominent long-term stability in one device. These contradictory features make the construction of adaptive transistors particularly challenging, because of the paradoxical demands of excitation and inhibition to the charge transport in the same conductive channel. OFETs have been considered to be promising candidates in sensory systems.^{5,14,18,74–76} In an OFET, three terminals (gate, source and drain) are separated by semiconductor layers and dielectric layers. When a voltage is biased between the gate and semiconductor, carriers can be induced at the dielectric–semiconductor interface and form a conductive channel. Through molecular design and device engineering, OFETs can convert external stimuli, such as light or pressure into electrical signals,^{18,74,77,78} which provided the possibility to construct organic adaptive transistors. Of particular note, the variation in device geometry can affect the involved interfaces, charge transport pathway and trapping mechanism. As a result, device geometry is an important factor that affects the functionalities of OFETs.

Our group demonstrated an OAT by introducing a composite dielectric layer (PVCN/PBTTT/PVA/PVCN) into the bottom-gate top-contact device (Fig. 7a).³⁰ The inbuilt charge-trapping interface (PBTTT/PVA) in the PVCN dielectric layer endows the device with separated charge transport and a self-adaptive interfacial trapping process, which contribute to the unique volatile shielding of the gating field. It therefore led to rapid and temporary decay of the carrier concentration in the conductive channel without diminishing the charge transport ability, allowing independent manipulation of two contradictory processes. The applied V_{GS} pulses induced a rapid and repeatable decay of the I_{DS} (Fig. 7b), illustrating the rapid short-term decay and prominent long-term stability for mimicking sensory adaptation. Interestingly, by modulating the electron-trapping dielectric or semiconductor layer, the device exhibits a fine-tuned decay constant ranging from 50 ms to 5 s (Fig. 7c), precisely matching the adaptation timescales in biological systems.^{59,79,80} Based on such unique properties, OATs can be utilized to emulate many advanced adaptation behaviors to dynamic stimuli. For example, the SA-OAT exhibited a notable

I_{DS} response with the increase of V_{GS} onset speed from 2.5 to 10 V s^{-1} (Fig. 7d and e). While applying a series of double-step V_{GS} , OATs exhibited high sensitivity (from 30 to 12 V^{-1}) when compared to non-adaptive devices (from 40 to less than 0.5 V^{-1}), due to the biomimetic suppression of input background (Fig. 7f and g). By exploiting the prominent adaptive properties, OATs serve as a powerful tool to enable biomimetic perception elements.

Recently, Lee *et al.* reported a flexible ferroelectric organic field-effect transistor (Fe-OFET) that can emulate the tactile sensory organ.¹⁴ This device is based on a ferroelectric nanocomposite gate dielectric layer of barium titanate nanoparticles (BT NPs) and poly(vinylidene difluoride–trifluoroethylene) (P(VDF-TrFE)) (Fig. 7h). When tactile stimulation is applied to the gate electrode, the alignment of dipoles is induced in the ferroelectric gate dielectric layer by the triboelectric–capacitive coupling effect. The resulting output current exhibits an increasing tendency with a decreasing slope throughout simulation until equilibrium is reached (Fig. 7i and j), which is akin to the SA sensation of human beings.

4.3. Device integration for bio-inspired perception applications

In realistic applications, adaptive devices have to operate under various stimuli, in order to enable good processing of external stimuli in a changeable environment. To fulfil this demand, an adaptive element should combine the detection of external signals and dynamic response to environmental conditions. Since these functionalities can be hardly achieved in a single device, the effective integration of sensing elements with adaptive devices is desirable for realizing advanced adaptation applications.

Integration of pressure sensors with OATs was carried out to verify the adaptation behaviours.³⁰ The OAT integrated circuits exhibit high sensitivity and decreased power consumption, and can be utilized to mimic FA events as human mechanoreceptors. By integrating tactile and temperature sensors that communicate through the asynchronously coded electronic skin (ACES) pulse signatures,⁴⁸ Tee's group designed a biomimetic model to mimic adaptation behaviours (Fig. 8a and b). Similar to biological counterparts,⁵¹ ACES-FA receptors respond to dynamic skin deformations as they transmit events immediately due to the increase (FA+) or decrease (FA–) in pressure, whereas ACES-SA receptors modulate static pressure intensity by event frequency. In addition, combining pressure- and temperature-sensitive transducers on a flexible substrate (Fig. 8c), simultaneous detection of thermotactile sensations could be achieved (Fig. 8d). The integration of different elements brings new opportunities for constructing multimodal devices with desired functionality. Arias *et al.* integrated the self-adapting mechanoreceptor with soft robotic hands to monitor real-time object manipulations (Fig. 8e).⁴³ The entire robotic gripper can be actuated and controlled with compressed air when pressurized by external objects. From the recorded signal outputs of the integrated mechanoreceptor when manipulated with an apple, “pick–hold–place” can be

clearly recognized as a result of the self-adaptive potentiometric-triboelectric hybridized sensing mode (Fig. 8f). The integrated soft robotic gripper is applicable for resolving complex stimuli with high accuracy, efficiency, and versatility in different sensing scenarios.

4.4. Towards active adaptation triggered by external stimuli

An ultimate goal of adaptive devices relies on the achievement of active adaptation to enable an autonomic response to varying external stimuli. In fact, light irradiation can principally offer a

powerful approach to modulate carrier concentration and even achieve active adaptation. Previous efforts have focused on achieving stable photocurrent generation for light detection.^{81,82} In contrast, a desired photoadaptive element must exhibit light intensity-dependent photoexcitation and inhibition functionalities in one device, in order to enable a direct response to stimuli.^{14,83} Under this circumstance, it is extremely challenging to design the so-called active adaptive devices with both transient photo-response and dynamic adaptation functionality.

Of particular note, a similar conundrum has been overcome in biological visual systems by using the coupled physiological mechanism. The related transmembrane transport of two different ions (Na^+ and Ca^{2+}) together with the associated gating dynamics leads to biological active adaptation.^{54,84–87} This unique mechanism offers an inspiration to achieve coupled manipulation of charge carriers on an OFET toward photoadaptive transistors. Our group reported an OAAT that exhibits light intensity-dependent active photoadaptation, which successfully imitated advanced adaptation behaviours of biological visual systems.⁴⁴ In this device, two functionally complementary bulk-heterojunctions are introduced in an OFET to function as the photoresponsive active layer and floating gate, respectively (Fig. 9a).

Output signals under various luminance stimuli exhibit fine-tuned transient photoresponse and dynamic adaptation in an automatic manner, and such a device can be classified into three distinctive models: from an ultraslow-adaptation ($\tau > 100$ s) to slow- ($1 < \tau < 100$ s) and fast-adaptation ($\tau < 1$ s) (Fig. 9b and c). Upon light irradiation, photovoltaic effect-induced photoexcitation occurs in BHJs to produce a transient detector response, while the accumulation of trapped carriers in the dielectric layer contributes to the photo-triggered dynamic decay of the gating field. The coupling of the photovoltaic effect in two BHJs and dynamic electron trapping in the dielectric layer allows the adaptive modulation of carrier concentration in the conductive channel, leading to active photoadaptation behaviours in a single element.

Fig. 9 An organic transistor with light intensity-dependent active photoadaptation. (a) An organic phototransistor with two complementary bulk-heterojunctions inspired by the visual adaptation in human visual systems. (b) Real-time photoresponse of the device to various stimulus luminance. (c) Correlation between decay constant and luminance. The device can be modulated from ultra-SA, to SA and FA models according to the light intensities. (d) Correlation between photosensitivity (P) and AAI extracted at 0.1 s with varied luminance. Photosensitivity increases along with light stimuli; herein, the active adaptation index (AAI) is defined as the photosensitivity change as a function of orders of luminance magnitude ($dP/d \log L$), which reflects the adaption ability with varying light stimuli. (e) A time and luminance schematic diagram of the predicted tendency of AAI. (f) Resulting current mapping of the OAAAT array under different conditions. With constant stimulus light intensity, the "T"-shaped image contrast decreases upon a bright-light background (10^4 cd m^{-2}) and gradually shows the spatially resolved discrimination enabled by active adaptation. Reproduced with permission.⁴⁴ Copyright 2021, Springer Nature.

To evaluate the performance of the OAAT, we defined AAI as a photosensitivity change along with the orders of luminance magnitude (Fig. 9d). The value remains less than 1 when the luminance stimulus is below 100 cd m^{-2} ; an enhanced luminance to 10^5 cd m^{-2} leads to notably increased AAI to 12.4. This tendency combined with the simulation results is comparable with the quasiquantitative value extracted from human visual systems,⁸⁸ suggesting the successful realization of bionic visual adaptation with the fabricated device (Fig. 9d and e). In addition, this smart device exhibits active photoadaptation behaviors including dynamic adaptive response to continuous stimuli, decay-to-recovery features and superior background-dependent discrimination (less than 2 s at $1 \times 10^4 \text{ cd m}^{-2}$) (Fig. 9f), suggesting that OAATs are promising systems to develop state-of-the-art active adaptation components.

4.5. Allowing diverse tactile adaptation by incorporating mechanical transduction

Certain adaptation applications require special types of devices with different development goals. For example, devices used to cope with dynamic force with high frequency demand FA elements, because in such conditions, a device needs to generate instantaneous electric signals only at the beginning and ending moments of stimulation, while SA elements are needed in response to static touch or pressure. To meet the requirement, devices that can imitate both SA and FA functions are in high demand. Transducers for mimicking SA typically rely on capacitive and piezoresistive effects as they can respond to static mechanical stimuli through continuous sensing signals (Fig. 10a).^{89,90} The capacitance (C) of a parallel plate capacitor is given by the equation $C = \epsilon_r \epsilon_0 A/d$, where ϵ_0 is the electric

Fig. 10 Construction of SA and FA devices through the piezoelectric effect. (a) Transduction mechanisms of capacitive and piezoresistive for mimicking slow adaptation mechanoreceptors. constant, ϵ_r is the relative permittivity, A is the area of overlap of the two plates, and d is the distance between the electrodes. A and D are easily changed by applying pressure, and thus cause the plate to deflect and the capacitance to change. Piezoresistive sensors transduce a change in the resistance of a device into an electrical signal. And, the change in contact resistance (R_c) between two materials created by the applied force (F) is the main source of the electrical signal change. Different from capacitive and resistive sensors, piezoelectric and triboelectric sensors can generate instantaneous electric signals under dynamic force stimuli, demonstrating capabilities similar to those of FA mechanoreceptors (Fig. 10b).^{91,92} Piezoelectricity refers to electrical charges generated in certain types of solid materials in response to an applied force, and the occurrence of electric dipole moments in solids contributes to the piezoelectric effect. The triboelectric effect is another commonly used transduction method only responding to dynamic stimuli, which is very suitable for mimicking FA.

Inspired by the perception functionalities of mechanoreceptors, a fingertip-like e-skin has been developed to discriminate FA and SA events (Fig. 10c).³⁸ The device is based on a vertical structure composed of a sliding and pressure sensing part to enable the capabilities of FA and SA mechanoreceptors. In a similar way, a hybrid porous microstructure (HPMS) e-skin composed of a triboelectric generator and an HPMS pressure sensor was demonstrated to mimic FA and SA behaviors simultaneously (Fig. 10d).⁴⁰ The structure of intermediate ridges also inspired studies to simulate different adaptation characteristics of mechanoreceptors. Ko *et al.* reported a multi-modal e-skin based on the interlocked microdome structure by using ferroelectric polymer composites composed of PVDF and reduced graphene oxide (rGO) (Fig. 10e).³⁷ In this device, the sustained static pressure can be detected by using the contact resistance change between the interlocked microdomes, while dynamic pressure detection can be achieved by using the piezoelectric sensing mode. Similarly, Ko and co-workers developed a pressure-sensitive e-skin in an interlocked geometry with a hierarchical ZnO nanowire (NW) array (Fig. 10f),⁹³ and the device exhibited fine-tuned adaptation behavior according to the intensity or frequency of force stimuli. By exploiting various transduction methods, such devices can serve as powerful tools to adapt to various force stimuli.

5. Conclusions and perspectives

Adaptive devices aim to adjust their behaviour actively to varying stimuli. Several progressive studies have been made both in materials and device engineering. In spite of these achievements, many challenges lie ahead. What is the most efficient way to manipulate charge transport in a dynamic manner and realize diverse active adaptation? How to realize an excellent match in signal output between adaptive devices and biological organisms? Can we integrate adaptive devices with sensing and synaptic elements to create novel perception

Fig. 11 The key aspects of adaptive devices that need to be focused on.

systems? To address these open questions, tremendous efforts should be made in the next five years.

Human beings possess multi-mode adapting ability to various stimuli. For example, the human skin contains numerous mechanoreceptors and thermoreceptors to adapt to pressure stimuli and temperature change. However, the reported adaptive devices are currently in the primary stage of mimicking adaptation behaviours individually. More efforts will be devoted to developing multi-mode sensory adaptation mechanisms (Fig. 11). So far, recreating sensory adaptation in solid-state devices mainly relies on tactile- and visual-adaptation devices. Further investigation on the physiological processes of human beings in order to mimic full adaptation functionalities is also urgently needed in the future. In addition, device integration will attract increasing research interest in demonstrating fascinating features of adaptive systems. On the one hand, device-to-device variability remains a key issue, leading to obstacles in constructing large area device arrays with high densities and good uniformity. On the other hand, adaptive devices should be integrated with sensors or other neuro-morphic devices to enable the next-generation artificial perception systems.

Ideally, an adaptive element should be based on a single device, in order to pursue the simplest geometry and minimized power consumption. This dreaming task is difficult to achieve not only because of the paradoxical requirements of signal excitation and inhibition in one device, but also it relies on the existence of different stimuli. An initial attempt has been made by creating an OAAT to endow a transistor with photoadaptation functionality.⁴⁴ Currently, this concept cannot be utilized to build other categories of active adaptation devices. Given that numerous sensing materials and device geometries have been developed, their incorporation with

controlled manipulation of charge trapping will accelerate the development of active adaptation devices in an unexpected way.

Fine-tuning sensitivity and decay speed play an essential role in developing state-of-the-art adaptive devices in accordance with the needs of environmental conditions. So far, the limited understanding of biological adaptation and adaptive devices impedes the realization of well-modulated adaptation performance. In-depth investigation regarding the relationship of energy levels of active materials and charge transport/trapping at interfaces should be paid more attention. More materials should be developed to meet the requirements of various application conditions. Stability is another concern of adaptation devices. Existing adaptive devices focus on the manipulation of electrical behaviour in one cycle, leaving the improvement of long-term stability an open issue.

In conclusion, the adaptation device is essential for artificial perception systems, but there is a long way to go to make adaptive devices possessing comparable adaptation ability to that of human beings. Further development should focus on materials and device engineering to achieve balanced modulation of charge transport and trapping. By resolving these challenges, we expect a bright future of adaptive devices towards a new smart world.
