The triggered self-assembly of surfactants into organized layers at aqueous interfaces is important for creating adaptive nanosystems and understanding selective ion extraction. While these transformations require molecular recognition, the underlying driving forces are modified by the local environment in ways that are not well understood. Herein, we investigate the role of ion binding and ion hydration using **cyanosurf**, which is composed of the cyanostar macrocycle, and its binding to anions that are either size-matched or mis-matched and either weakly or highly hydrated. We utilize the supra-amphiphile concept where anion binding converts **cyanosurf** into a charged and amphiphilic complex triggering its self-organization into monolayers at the air–water interface. Initially, **cyanosurf** forms aggregates at the surface of a pure water solution. When the weakly hydrated and size-matched hexafluorophosphate (PF₆[−]) and perchlorate (ClO₄[−]) anions are added, the macrocycles form distinct monolayer architectures. Surface-pressure isotherms reveal significant reorganization of the surface-active molecules upon anion binding while infrared reflection absorption spectroscopy show the ion-bound complexes are well ordered at the interface. Vibrational sum frequency generation spectroscopy shows the water molecules in the interfacial region are highly ordered in response to the charged monolayer of **cyanosurf** complexes. Consistent with the importance of recognition, we find the smaller mis-matched chloride does not trigger the transformation. However, the size-matched phosphate (H₂PO₄[−]) also does not trigger monolayer formation indicating hydration inhibits its interfacial binding. These studies reveal how anion-selective recognition and hydration both control the binding and thus the switching of a responsive molecular interface.

Introduction

Supra-amphiphiles^{1–3} are an emerging class of surfactants that become surface active and self-organize into monolayers, bilayers, micelles, and liposomes upon the pre-programmed binding of another molecule or ion. Their responsive organization⁴ is believed to impact diverse areas ranging from the creation of adaptive materials for aqueous nanosystems, like artificial light-harvesting systems,⁵ drug delivery,^{6,7} and vesicle nanoenzymes,⁸ through to the third-phase behaviors of separation systems⁹ occurring in the liquid–liquid extraction of

ions¹⁰ used in the nuclear fuel cycle¹¹ and in the capture of critical elements.^{12,13} For example, inverse micelles form when amphiphiles extract anionic complexes of lanthanide ions¹⁴ from nitrate-rich aqueous solutions to organic solutions. A recent example¹⁵ showed the triggered transformation of a monolayer into a bilayer upon ion binding at the air–water interface. Some of these triggered phase changes do not follow expected trends and are instead ion-specific¹⁶ suggesting that we have an incomplete understanding of how the underlying ion-binding events are modified by the aqueous interface.^{17–23} While there is a kinship between binding-triggered extraction surfactants and supra-amphiphiles, the extraction systems do not typically use complementary receptors. Similarly, supra-amphiphiles are not routinely studied using well-defined monolayers. Thus, we see an opportunity to better understand the underlying driving forces by combining pre-programmed ion-binding sites with formation of Langmuir monolayers.²⁴ Herein, we use the well-known recognition chemistry of cyanostar macrocycles²⁵ to examine how the supra-amphiphile **cyanosurf** (Fig. 1a) self-organizes into monolayers upon the binding of specific anions (Fig. 1b and c). We leverage the

(b) Anion-driven transformation of cyanosurf into a supra-amphiphile by formation of a 2 : 1 complex with surfactant properties. (c) Molecular recognition by cyanosurf at the interface allows the charged supra-amphiphile to spontaneously self-organize into a monomolecular film (monolayer) at the air–water interface.

selective binding of larger anions like perchlorate (ClO_4^-), which serves as an analog of the radioactive pertechnetate (TcO_4^-),²⁶ and compare it to phosphate (H_2PO_4^-) to set up a competition between anion recognition and anion hydration.

The self-organization of supra-amphiphiles has been programmed to respond to various recognition chemistries,^{27–29} *e.g.*, host–guest binding,³⁰ electrostatics,³¹ and metal cation binding.³² By contrast, the use of anion binding is relatively rare despite the importance of anionic species in extraction studies¹² and in the capture of other environmentally relevant anions, *e.g.*, phosphate³³ and nitrate (NO_3^-)³⁴ as fertilizer, and bicarbonate (HCO_3^-)^{35,36} as carbon dioxide. The few examples of anion-triggered supra-amphiphiles leverage macrocycle-ion binding events. Anion- π interactions used by Wang³⁷ show generation of vesicles upon binding anionic surfactants, *e.g.*, sodium dodecylsulfate. A second set of examples by Sessler use ion-pair binding. In one case, iron difluoride (FeF_2) drives formation of micelles in aqueous solution.³¹ Another uses receptor-modified diblock copolymers that form inverse micelles under liquid–liquid extraction conditions upon binding ion pairs of alkali cations and halides, like cesium

fluoride (CsF).³⁸ Thus, the reliable recognition chemistry of macrocycles allow the chemical specificity of the binding event underpinning the supra-amphiphile effect³⁹ to be well defined.

To complement the role of the receptor in understanding and controlling triggered phase changes, the study of monolayers at the air–water interface also serves as a well-defined model of more complex soft-matter systems.⁴⁰ For instance, monolayers often produce greater degrees of local ordering and more well-defined interfacial regions than vesicles and micelles⁴¹ or the inverse micelles in the third phase.^{14–16} The analysis of monolayers also benefits from a set of complementary techniques that can reveal details of the resulting interfacial phase behavior and structures. Thus, the molecule-ion binding that occurs at air–water interfaces provides a well-defined environment to help understand design principles of interfacial recognition chemistry that cannot be achieved in the study of bulk soft-matter phases.^{21,41,42} Pioneering works from Kunitake^{41,42} and recent work from our groups^{17–19} have also shown that the air–water interface offers a lower dielectric constant that helps enhance affinity to offset the cost of anion dehydration upon binding. To the best of our knowledge,

however, the triggered assembly of supra-amphiphiles into monolayers at the air–water interface have not been studied to help deconvolute the specificity of ion binding into the competing effects of recognition and hydration.

Herein, we study the structures, selectivities, and the driving forces of the anion-triggered self-organization of a supra-amphiphile at air–water interfaces. For this purpose, we tailored a cyanostar macrocycle, called **cyanosurf**, to generate surfactant properties upon anion binding. Cyanostar macrocycles show strong size-dependent binding $\sim 10^{12} \text{ M}^{-2}$ in organic solvents with large and charge-diffused anions, such as PF_6^- and ClO_4^- .²⁵ Thus, we expect these hydrophobic anions to bind and trigger amphiphile formation leading to self-organization as a monolayer.²⁵ To verify that binding is defined by the macrocycle's preprogrammed recognition properties, we compared the response to the smaller Cl^- anions, which has a low affinity for the macrocycle. To evaluate the role of hydration, we examined binding of H_2PO_4^- . While this anion binds well to cyanostar in organic solutions,⁴³ it has a high hydration energy. Thus, we set up a competition between the two driving forces of recognition and hydration. The interfacial binding and phase formation properties were studied using surface pressure–mean molecular area isotherms, Brewster angle microscopy (BAM) imaging of the surface, infrared reflection absorption spectroscopy (IRRAS), and sum frequency generation spectroscopy (SFG). These studies show that the **cyanosurf** molecules alone form an aggregate on pure water corresponding to the initially hydrophobic character of **cyanosurf**. Addition of PF_6^- or ClO_4^- anions in the subphase as sodium (Na^+) salts initiates **cyanosurf** to self-organize into a well-ordered monolayer. Interfacial anion binding produces the supra-amphiphiles with the negatively charged **cyanosurf**-anion complex serving as aqueous anchors for monolayer formation. Addition of the hydrophilic Cl^- and H_2PO_4^- anions does not produce interfacial complexes. These studies show how interfacial binding and triggered monolayer formation are a balance between the pre-programmed molecular recognition and the anion's hydration properties. The combination of these

factors is responsible for the binding of specific ions and needs to be considered in the design of supra-amphiphiles and extraction systems alike.

Results and discussion

Molecular design and synthesis

We designed an anion-triggered surfactant-forming receptor, **cyanosurf**, that is based on the cyanostar macrocycle. These macrocycles are also shape-persistent with well-defined and rigid structures and for this reason, the contribution of conformational flexibility to the binding and self-organization of the macrocyclic core can be neglected. This factor enables a more direct attribution of the resulting ion-triggered phase behavior to the intrinsic recognition properties of the macrocycle.

To adapt this compound to supra-amphiphile formation, we incorporated three long octadecyl tails for interfacial anchoring. This target compound was made by coupling (Scheme 1) the iodo-cyanostar macrocycle, **1**, with tris-alkoxy-5-ethynylbenzene, **2**, under Sonogashira conditions in 45% yield according to previously reported procedures.^{44,45} Compound identity was confirmed using ^1H , $^{13}\text{C}\{^1\text{H}\}$ NMR spectroscopy and high-resolution mass spectrometry.

Self-association behavior in organic solution

Cyanosurf is expected and found to display similar properties as those of the parent cyanostar²⁵ albeit with a greater propensity towards self-association. Variable concentration UV-Vis and NMR spectra are consistent with a high degree of self-association in chloroform. From 1 to 100 μM , the absorption spectra (Fig. 2a) show both substantial decreases in extinction coefficient from 60 000 to 8000 $\text{M}^{-1} \text{ cm}^{-1}$ with substantial peak broadening. The extent of broadening produces a flat-topped band suggesting that it might have been an artifact of the measurement. However, all the absorbance values were below 1.0. These effects are all typical of self-association.⁴⁶ For this reason, the data was analyzed according to the simplest

Scheme 1 Synthesis of **cyanosurf** macrocycle.

Fig. 2 (a) Variable concentration studies of cyanosurf in organic solution observed using UV-Vis absorption (1–100 μM , CHCl_3) normalized to the extinction coefficient and (b) analyzed according to an isodesmic model of self-association (325 nm white squares, 310 nm red circles).

isodesmic model of self-association, so-called equal-K model⁴⁷ (ESI⁺), and found to be consistent with a large self-association constant of over 10^5 M^{-1} .

^1H NMR spectroscopy (Fig. 3a) was used to provide insights into structural changes accompanying self-association. As the concentration is raised from 100 μM up another two orders of magnitude to 10 mM, the aromatic ^1H NMR protons display upfield shifts indicative of π stacking.⁴⁶ These shifts are seen in all the inner and outer cyanostar protons (H_A , H_B , H_C , H_D). Notably, however, the protons (H_E) on the trialkoxy-substituted phenylene do not change position. This observation suggests that any association between neighboring molecules do not bring these pendant phenylenes into contact with each other. Across the same concentration range, we also observe (Fig. 3b) an increase in emission from the solution. This type of signature is often associated with the suite of phenomena broadly described as aggregation-induced emission.⁴⁸ Taken together, these spectroscopies provide evidence that cyanosurf can support extensive self-association in organic chloroform solutions.

Anion-binding triggered monolayer formation

The potential for interfacial anion binding leading to supramolecular amphiphile formation and subsequent surface self-assembly (Fig. 1b and c) of cyanosurf molecules with ClO_4^- , PF_6^- ,

Fig. 3 Variable concentration studies of cyanosurf in organic solution (a) observed using ^1H NMR spectra recorded 0.1–10 mM (CDCl_3 , 298 K, 600 MHz) and (b) a photograph of the corresponding NMR tubes recorded under UV light illumination.

H_2PO_4^- and Cl^- anions was investigated. Surface pressure–mean molecular area (Π - A , Fig. 4) isotherms were used to evaluate the interfacial recognition events between the neutral

Fig. 4 The Π - A isotherms of the cyanosurf molecules on water (black trace) and on a 10 mM aqueous solution of the sodium (Na^+) salts of (a) hexafluorophosphate (PF_6^-) (blue trace), (b) perchlorate (ClO_4^-) (brown trace), (c) dihydrogen phosphate (H_2PO_4^-) (orange trace), and (d) chloride (Cl^-) (green trace), respectively.

cyanosurf and aqueous anions. The samples were prepared by adding a known amount of the **cyanosurf** to the water phase as a chloroform solution and allowing the organic solvent to evaporate. Subsequently, Π - A isotherms of the **cyanosurf** deposited onto aqueous solution surfaces were recorded (black lines, Fig. 4) by compressing any surface-anchored species to smaller areas and measuring their growing surface pressures. The isotherms were also recorded with the **cyanosurf** deposited on solutions with 10 mM of PF_6^- (blue line, Fig. 4a) and ClO_4^- (brown line, Fig. 4b) in the aqueous solution. With these anions present, there is a significant expansion to larger mean molecular areas (MMAs) compared to the isotherm on pure water (black lines). With **cyanosurf** on aqueous solutions of PF_6^- , we see a mean molecular expansion from 65 to 122 \AA^2 per molecule ($\Pi = 10 \text{ mN m}^{-1}$) and a lift-off point above 170 \AA^2 per molecule. The isotherm of the **cyanosurf** molecule on ClO_4^- also shows a similarly large expansion of the mean molecular area to 125 \AA^2 per molecule ($\Pi = 10 \text{ mN m}^{-1}$) with a lift-off point of $\sim 170 \text{\AA}^2$ per molecule. Observation of larger mean molecular areas upon monolayer compression indicates that **cyanosurf** molecules display substantially different organization at the interface, which is consistent with the binding of PF_6^- and ClO_4^- anions to the cyanostar core seen in organic solution.²⁵

The isotherms on PF_6^- and ClO_4^- show multiple phases. Lift-off is usually associated with the onset of a liquid-expanded

phase. For both PF_6^- and ClO_4^- , there also appears to be a turnover around 5 mN m^{-1} (150 \AA^2 per molecule) consistent with passing through a coexistence region containing both the liquid expanded and liquid condensed phases, and then a phase transition to the liquid condensed phase around 10 mN m^{-1} . In the case of both anions, we see a second (~ 10 – 20 mN m^{-1}) and third (~ 40 – 55 mN m^{-1}) phase. These are usually associated with liquid-condensed phases having high and low tilting, respectively, and an intermediate coexistence region (~ 20 – 40 mN m^{-1}) in which both tilted phases exist. These transitions occur at slightly different pressures and MMAs for the two anions. Overall, both anions show a gradual nonlinear increase in surface pressure upon compression until a collapsed phase is produced at around 55 mN m^{-1} (70 \AA^2 per molecule). We attribute the behavior seen in the isotherm to formation of expanded and then condensed monolayers of the supra-amphiphiles.

Contrary to the significant expansion seen in the cases of PF_6^- and ClO_4^- , the Π - A isotherms of **cyanosurf** with 10 mM of H_2PO_4^- or Cl^- present in bulk solution show a negligible change (Fig. 4c and d). This observation suggests that the interfacial arrangement of the **cyanosurf** molecules is unaltered when H_2PO_4^- and Cl^- are individually present in the aqueous solution. The negligible response to chloride is consistent with the selectivity preferences of the macrocycle,²⁵ which disfavors

smaller anions. However, phosphate is a size-matched anion that displays strong binding⁴⁹ in organic solutions. On that basis alone, it is expected to display similar interfacial binding as PF_6^- and ClO_4^- . However, the isotherm results indicate otherwise. To corroborate the results from the isotherm studies, aqueous surface imaging was undertaken.

Surface organization by Brewster angle imaging

BAM images provide real-time $\sim 1 \mu\text{m}$ resolution aqueous surface imaging of the morphological changes in the packing

structure of the **cyanosurf** molecules throughout the Π -A isotherm. The bright areas of the images correspond to regions enriched in molecular species (non-solvent molecules) at the surface and the dark areas are poor in surface active molecules (and are therefore water-rich). The increase in brightness scales with changes in refractive index relative to the bulk solution. For this reason, the brighter areas of the image correspond to either more dense and/or assemblies of molecules enriched at the surface that extend into three-dimensions (3D). Consequently, 2D monomolecular monolayer films are less bright

Fig. 5 BAM images corresponding to the compression of the **cyanosurf** molecules on (a) H_2O and the aqueous solutions of the sodium salts at 10 mM of (b) Cl^- , (c) H_2PO_4^- (d) PF_6^- , and (e) ClO_4^- , respectively. Images (a)–(e) correspond to different mean molecular areas (MMAs) to show the range of the Π -A isotherms. The blue color in the image is artificial for better contrast; the beam focus gives rise to the central brightness of (d) and (e). The scale bar is $50 \mu\text{m}$.

compared to surface-aggregates that are 3D. It is evident from the BAM imaging that there are significant amounts of 3D structures with **cyanosurf** on water, on phosphate, and on the chloride solutions with the brightness increasing upon compression of the monolayer (Fig. 5a–c). The 3D structures begin to form when the **cyanosurf** molecules are at low average film density with MMAs = 180, 120, and 120 Å² per molecule for pure water, H₂PO₄[−] and Cl[−], respectively, even though the surface pressure has yet to lift off at $\Pi = 0$ mN m^{−1}. The observation of 3D structures (*i.e.*, aggregates) of the **cyanosurf** macrocycle at the interface is consistent with the self-association phenomena for shape-persistent macrocycles in bulk solution.^{46,50,51} Thus, the **cyanosurf** molecules exist in an aggregated form in chloroform prior to deposition and retain that form on the surface of water. According to the BAM study, the presence of H₂PO₄[−] and Cl[−] anions in the aqueous solution are not able to induce a re-organization of the aggregated **cyanosurf** molecules into an ordered monolayer through interfacial binding.

In comparison, we observed neat and homogeneous film formation when **cyanosurf** was deposited on aqueous solutions of PF₆[−] and ClO₄[−]. BAM imaging shows (Fig. 5d) a homogeneous **cyanosurf** monolayer is formed with PF₆[−] in the expanded region at 180 Å² per molecule in stark contrast to bright 3D structures observed with water, phosphate, and chloride. The molecular density increases upon compression and we see increasing brightness for the neat film (Fig. 5d). We observe a similar result for **cyanosurf** on ClO₄[−] solutions (Fig. 5e). Clearly, addition of PF₆[−] and ClO₄[−] drives 2D monolayer film organization. The only mechanism by which this occurs is for transformation of the hydrophobic macrocycle into a supra-amphiphilic complex upon anion binding (Fig. 1b). Thus, the charged complex orients into the aqueous subsurface while the alkyl chains are directed towards the air side of the aqueous interface to help with film organization.

Molecular model of the anion complexed supra-amphiphile

Models of the possible amphiphilic complexes (Fig. 6) that can self-assemble upon anion binding at the interface are proposed. Under the conditions of the experiment there is an excess of anions (ClO₄[−], PF₆[−]) in the subphase. Excess anion typically favors 1 : 1 binding stoichiometries (Fig. 6a). In the case of the cyanostar macrocycles with ClO₄[−] and PF₆[−], however, they prefer 2 : 1 complexation by forming a π -stacked seam (Fig. 6b). We also know that the steric gearing between *tert*-butyl substituents on the π -stacked macrocycles predefines a limited number of macrocycle–macrocycle rotational angles at $\sim 36^\circ$ (Fig. 6b) or 108° (Fig. 6c) relative to each other.⁵² An angle of 180° is also possible but would lead to bolophiles with the large trialkoxy chains at opposite ends of the complex. Modelling shows that the smaller angle (36°) has the most efficient packing of space. The six alkoxy chains are better size-matched to the $\sim 20 \text{ \AA} \times 8 \text{ \AA}$ footprint of the **cyanosurf**-anion complex of the hydrophilic group. The fact that this complex involves two macrocycles, it defines a cross-sectional area of 80 Å² per molecule, which is the MMA value approached at higher surface

pressures for PF₆[−] and ClO₄[−] (Fig. 4). While this MMA is also similar to the surface density of the 1 : 1 complex (Fig. 6a), the 2 : 1 complexes are favored by these anions.

The observation of larger MMAs seen initially, *e.g.*, $\sim 170 \text{ \AA}^2$ per molecule at lift-off, suggest that different arrangements are possible. These include a different rotation angle (108°) with larger MMA (Fig. 6c) or tilting (Fig. 6d) could exist through the liquid-expanded phases. In the putative liquid-expanded and co-existence regions, the 2 : 1 complexes may have a range of local structures. These include mixtures of the 36° and 108° rotational complexes as well as a variation in the tilt angles. At the high-density liquid-condensed region generated under high compression ($\Pi = 10\text{--}55$ mN m^{−1}), however, the 2 : 1 stoichiometries favored by the anion-recognition properties of cyanostar²⁵ are likely to produce 36° rotations between the two complexed macrocycles.

Surface spectroscopy of the interfacial anion-bound complexes

In order to better understand some of the molecule-level details of the binding events occurring between **cyanosurf** and anions at the interface, spectroscopic studies using infrared reflection absorption spectroscopy (IRRAS) were performed. The IRRAS data was collected at 150 Å² per molecule coinciding with the liquid expanded region that shows a highly ordered monolayer by BAM analysis and is assigned to formation of the 2 : 1 supra-amphiphile complex. The IRRAS data are plotted as reflectance-absorbance (RA) spectra, which is given as $RA = -\log(R_c/R_0)$, where R_c is the reflectivity of the **cyanosurf** surface and R_0 is the reflectivity of the subphase solution, *i.e.*, either water, PF₆[−] or ClO₄[−] aqueous solutions. On account of the fact that the spectra of the PF₆[−] or ClO₄[−] subphase solution is present in both the numerator and denominator leads to IRRAS signals being sensitive solely to the **cyanosurf**-bound ions. Downward peaks are observed, as expected for reflectivity studies in this optical geometry.⁵³ There are clear vibrational signatures from perchlorate and hexafluorophosphate anions bound to the **cyanosurf** molecules in the monolayers. Broad peaks appear for **cyanosurf**-PF₆[−] (Fig. 7a) and **cyanosurf**-ClO₄[−] (Fig. 7b) at approximately 846 and 1110 cm^{−1}, and are assigned to the hexafluorophosphate antisymmetric (ν_{as} P-F) and perchlorate asymmetric (ν_{as} Cl-O) stretching modes, respectively.^{54,55} The presence of these peaks supports the binding of PF₆[−] and ClO₄[−] to the **cyanosurf** molecules. Similar anion vibrational signatures for phosphate in the presence of the **cyanosurf** molecules are absent (ESI, Fig. S4†).

The alkyl stretching region provides useful insight into the molecular organization within the monolayer. With **cyanosurf** on water (black traces, Fig. 7c and d), the IRRAS spectra show two distinct albeit weak peaks at 2852 and 2920 cm^{−1} that are assigned to the CH₂ symmetric and asymmetric stretches, respectively. When comparing these alkyl modes to those of the **cyanosurf** on aqueous solutions of PF₆[−] and ClO₄[−], the intensities of both peaks have increased substantially and are blue shifted (Fig. 7c and d). A third peak at 2963 cm^{−1} also becomes more prominent for **cyanosurf** on PF₆[−] and ClO₄[−] and is

Fig. 6 Molecular models of the supra-amphiphile complexes at the air–water interface as (a) a 1 : 1 complex, (b) 2 : 1 complexes with either $\sim 36^\circ$ or (c) $\sim 108^\circ$ rotation angles that are defined by the sterically-gated *tert*-butyl groups on the macrocycles. (d) Tilted arrangements of the supra-amphiphiles.

assigned to the asymmetric stretch of the terminal CH₃ groups. We attribute the observed changes in intensity to the transition from 3D aggregates of the **cyanosurf** to a monolayer of the **cyanosurf**-anion complex seen by BAM imaging. The increase in the IRRAS intensity of the vibrations associated with the anions and the CH modes of the alkyl chains that occur with anion complexation indicates that interfacial complexation of the anions and re-organization into a homogeneous monolayer film. For H₂PO₄[−] and Cl[−] solutions, we observe a substantial loss of the **cyanosurf** methylene signature compared to that on water (ESI[†]), in opposition to what is observed from **cyanosurf** on PF₆[−] and ClO₄[−] solutions. This observation is consistent with the picture of anion-triggered **cyanosurf** surface complexation with PF₆[−] and ClO₄[−] and not with the H₂PO₄[−] and Cl[−] anions.

As seen in the BAM imaging, **cyanosurf** prefers to retain an aggregated form on water and is not distributed as

a homogenous monolayer. In this situation, the average spectra recorded using IRRAS is a combination of mostly the bare water surface and any of the 3D aggregated structures of **cyanosurf**. This averaging produces the weak signature of the hydrocarbon chains observed in the IRRAS spectra. However, in the presence of the PF₆[−] and ClO₄[−], the **cyanosurf** molecules bind to these anions likely as a 2 : 1 sandwich complex (Fig. 6b and c) and self-organize into the monolayer (Fig. 1c). With the **cyanosurf** macrocycles bound to the anions on the surface, the hydrocarbon chains organize towards the air side of the interface. This anion-driven transition of the **cyanosurf**-aggregates (solid phase, 3D aggregates) to the **cyanosurf**-monolayer (amphiphilic phase) gives rise to a blue shift of the ν_s CH₂ and ν_{as} CH₂ stretching modes. The alkyl chains in the aggregated phase are seen to vibrate at lower frequencies indicating that either some or all of the chains are organized in the all-*trans* methylene-

Fig. 7 IRRAS spectra showing **cyanosurf** reorganization upon anion binding. The spectrum of the **cyanosurf** molecules on water is shown as a black trace for (a)–(d). The spectra of the **cyanosurf** molecules with 10 mM of the sodium salts of (a) and (c) ClO_4^- (brown) and (b) and (d) PF_6^- (blue) at a MMA of 150 \AA^2 per molecule.

methylene conformations. These conformations facilitate packing and thus intermolecular interactions between the adjacent chains. Transformations from all *trans* to *gauche* are commonly observed with infrared frequency shifts.^{53,56} More *gauche* defects are consistent with higher methylene stretch frequencies (blue shift). Additional *gauche* defects can be accommodated in the amphiphilic monolayer when there is more space available for the chains and when organization depends less on the inter-alkyl interactions. In the monolayer arrangement, it is clear that the anion-bound complex possesses a larger footprint than its six tails alone and the resultant structure allows room for some disorder in the chains. Therefore, the charged macrocyclic headgroup of the **cyanosurf** complexes likely plays a larger role than the tails on ordering the monolayer.

Spectroscopy of the interfacial hydration layer defined by the **cyanosurf**-anion monolayer

To investigate the surface hydration and water alignment effects that are induced by the organized **cyanosurf**-anion monolayer in the liquid-expanded region, we used sum frequency generation (SFG) spectroscopy. This technique selectively probes the topmost layers of aqueous surfaces. In addition, the presence of charged interfaces greatly enhances the depth that contributes to the SFG signal. The spectra were taken in the ssp polarization combination (s-SFG, s-visible, p-infrared) in the region from 3800 to 3000 cm^{-1} . SFG spectra of neat water and 10 mM salt solutions were recorded first in the absence of **cyanosurf**

(Fig. 8a). The neat water spectra (black trace) all consist of a broad band below 3600 cm^{-1} corresponding to the hydrogen-bonded water and a sharp peak centered at $\sim 3700 \text{ cm}^{-1}$ assigned to dangling OH bonds from the topmost layer of water.

Recent SFG studies from the surfaces of low-concentration salt solutions show that the intensity of the lower frequency OH stretch region ($< 3300 \text{ cm}^{-1}$) corresponds to water molecules in sub-surface layers. As a consequence, the signal intensity stems from the bulk $\chi^{(3)}$ contribution arising from an electric double layer.^{57–59} In this situation, the transition dipole moments of the water molecules align normal to the surface and result in an increase in the SFG intensity at $\sim 3200 \text{ cm}^{-1}$. We do not observe any such changes in the SFG spectra upon addition of the salt at 10 mM concentration without the **cyanosurf**. Therefore, use of such low salt concentrations produce very little change in the organization of surface water.

SFG spectra recorded in the presence of the **cyanosurf** molecules show dramatic changes upon selective anion binding (Fig. 8b). First, the SFG spectra for **cyanosurf** on water, chloride and phosphate solutions show similar features when compared to the SFG spectra recorded without the **cyanosurf** (Fig. 8a). This similarity reinforces our observations that there is little interaction between the **cyanosurf** receptor and Cl^- or H_2PO_4^- anions.

For the liquid-expanded phase composed of the supra-amphiphilic 2 : 1 **cyanosurf**-anion complexes on PF_6^- and ClO_4^- aqueous solutions (Fig. 8b), however, we observe a dramatic enhancement in the intensities of “OH” stretching

Fig. 8 Sum frequency generation spectra of the: (a) H₂O, Cl⁻, H₂PO₄⁻, PF₆⁻, and ClO₄⁻ aqueous solutions without the **cyanosurf** shown with a baseline offset for clarity, (b) and with the **cyanosurf**. (c) Schematic representation of the anion-induced organization of the **cyanosurf** monolayer. Spectra were obtained after an equilibration time of 10 minutes following the spreading of **cyanosurf** to a constant MMA of 150 Å² per molecule.

modes for water at ~ 3150 cm⁻¹. This enhancement is attributed to the $\chi^{(3)}$ effect, which is also termed the $\chi^{(2)}$ diffuse layer ($\chi_{DL}^{(2)}$),⁶⁰ and is associated with the alignment of water stemming from large electrostatic fields. With the addition of PF₆⁻ and ClO₄⁻, this enhancement is more than 10 times higher when compared to all other spectra. The electrostatic field that aligns the water molecules and gives rise to the enhanced SFG signal is a result of the self-organization of the amphiphilic **cyanosurf**-anion complexes into charged monolayers at the surface of water. Alignment of the surface and subsurface water molecules thus removes the solution centrosymmetry allowing more water molecules to contribute to the nonlinear SFG polarization response. This behavior is consistent with reports by several groups of charged surfactant-water interfaces.^{61–63}

Chemical and physical contributions to the driving forces of interfacial anion recognition

The selective response of **cyanosurf** to PF₆⁻ and ClO₄⁻ but not Cl⁻ follows from the size-dependent binding dictated by the macrocyclic core but does not explain the response to phosphate. This anion has been shown to form oligomers that

recruit as many as four cyanostar macrocycles into a large assembly⁴⁹ with binding energies on par with PF₆⁻ and ClO₄⁻. Yet, by all measures, we see a negligible molecular recognition response to the H₂PO₄⁻ anion. This anomaly can be explained by taking into account the fact that H₂PO₄⁻ anions are highly hydrated (-465 kJ mol⁻¹).^{64,65} By comparison, the lower dehydration penalties are easier to pay in the case of the less hydrated PF₆⁻ and ClO₄⁻ anions (-71 and -205 kJ mol⁻¹, respectively).

The observation that hydration energies play a role is consistent with prior work revealing that positively charged receptors are key to driving interfacial phosphate binding through electrostatics-assisted hydrogen bonding.¹⁷ Clearly the neutral cyanostar macrocycle's binding energy is not able to offset the high hydration energy of the H₂PO₄⁻ anion. That prior work also showed that the interfacial phosphate binding energies were enhanced on order 10 000× over bulk aqueous solution. To provide a measure of the affinity, we measured the binding of ClO₄⁻ to the monolayer. We used a MMA of 150 Å² per molecule and fit the data to a 2 : 1 binding model to obtain a value of 1000 M⁻¹. We cannot compare this value to aqueous

solution because **cyanosurf** or any of its homologs are not soluble in water. The only comparison we have is to MeOH-CHCl₃ solutions where affinity is as high as 10¹² M⁻¹. We attribute the fall-off in stability to the steep cost of dehydration.

Conclusion

We provide the first account of supra-amphiphilic film formation based on anion-selective recognition and its use to understand the driving forces that govern interfacial anion binding. The **cyanosurf** molecules are initially aggregated, however, upon binding perchlorate (ClO₄⁻) and hexafluorophosphate (PF₆⁻) from aqueous solutions they become organized as monolayers. Without the binding, the **cyanosurf** molecules remain in an aggregated state on pure water and on phosphate and chloride aqueous subphases. For the PF₆⁻ and ClO₄⁻ anions, surface pressure isotherms reveal large expansion signatures with well-behaved phases. Aqueous surface microscopy shows production of an ordered amphiphilic 2D monolayer phase. Infrared reflectivity studies show vibrational spectra of surface anion modes indicative of their complexation and a reduction in chain organization indicating the charged headgroup dictates monolayer ordering. Vibrational sum frequency generation spectroscopy reveals that the monolayer formed upon **cyanosurf**-mediated binding of ClO₄⁻ and PF₆⁻ produces a substantial negatively-charged interface that aligns water molecules perpendicular to the surface plane. The same outcomes are not present with Cl⁻ and H₂PO₄⁻. Chemical selectivity is conferred on the interfacial molecular recognition by the size-dependent binding of **cyanosurf** to ClO₄⁻ and PF₆⁻ anions. Physical selectivity is conferred on the interfacial recognition by the hydration energy penalty that disfavors phosphate. Chloride binding is disfavored on chemical and physical grounds. Phosphate binding is disfavored on physical grounds alone. The study of anion binding induced reorganization of the **cyanosurf** monolayer helps deepen our understanding of molecule-mediated recognition phenomena that trigger formation of soft-matter phases at aqueous interfaces.

Author contributions

L. Y., A. S., W. Z., J. F. N. and Y. C. conducted the studies and data analysis. L. Y. and W. Z. wrote the original draft. A. H. F. and H. C. A. conceptualized and supervised the research. All authors contributed to the manuscript writing and editing.
