Incorporation and modification of fatty acids in cyanobacterial natural products biosynthesis

Pedro N. Leão, ^a Teresa P. Martins, ^{ab} Kathleen Abt, ^{ab} João P. A. Reis, ^{ab} Sandra Figueiredo, ^a Raquel Castelo-Branco ^{ac} and Sara Freitas ^{ac}

Fatty acid-derived alkyl chains are often found in natural products, where they can exert a number of different functions, most notably biological membrane interactions. Such alkyl chains are difficult to modify regio- and stereoselectively, since most positions are distant from any directing functional group. Chemical and biochemical diversification of these moieties is therefore a challenge, and most organisms do not modify alkyl moieties to a great extent. Still, one particular group of microorganisms – cyanobacteria – display not only a large number of fatty acid-incorporating natural products, but also modify these to a great extent. Here, we provide an overview of the unique fatty acid metabolism of cyanobacteria in the context of natural products biosynthesis. We cover the diverse range of fatty acid incorporation mechanisms that these organisms use to recruit and commit fatty acids to natural products biosynthetic pathways. A variety of alkyl chain decorations and modifications that are found in cyanobacterial natural products are highlighted, illustrating the rich enzymatic arsenal that these organisms have evolved to diversify fatty acid-derived alkyl chains.

Introduction

A number of bioactive small molecules, including drugs, contain fatty acyl-derived moieties, which are important for interactions with membranes, signaling, bioactivity or biofilm formation.^{1–3} For example, a number of lipopeptide antibiotics require an *N*-acylated tail for activity,⁴ colibactin uses an acyl chain as part of a pro-drug mechanism⁵ and acylation is proposed to prevent certain siderophores from diffusing away from the cells before binding iron.⁶ Despite the well-established importance of such lipid tails, medicinal chemistry efforts do not systematically employ conjugation of lipid moieties such as medium- and long-chain fatty acids to pharmacophores.^{7,8} Even in biological chemistry, modification of lipid tails is usually restricted to chain length and unsaturation. The reason behind this is likely the same in the fume hood as in the living cell – once generated, alkyl chains are difficult to selectively modify due to a high C–H bond energy and the distance to directing functional groups. Most organisms lack the biochemical tools to modify such saturated fatty acyl groups to a great extent, other than unsaturation and functionalization in alpha or beta positions. These modifications

are often introduced during biosynthesis or degradation of fatty acids and take advantage of carbonyl chemistry and the acidity of the alpha-carbon. Still, some widespread desaturases act regioselectively on fully saturated alkyl chains.⁹ Perhaps to circumvent the challenges with installing functionalities in specific alkyl chain positions, many organisms – in particular bacteria and fungi – have evolved polyketide synthases that modify the alkyl chain as it grows. These pathways enable considerable structural diversification of the growing chain, but are difficult to engineer and to use in biocatalysis/metabolic engineering as they are part of mega-enzyme complexes that require multiple proteins/domains to interact spatially to perform their function.¹⁰ Nevertheless, notable advances have been made in this field, such as the recent reports on fluorine incorporation into PKS pathway products.^{11,12}

Members of the bacterial phylum Cyanobacteria frequently incorporate fatty acids into their natural products.^{13,14} A large variety of acyl or alkyl moieties, ranging usually from C4 to C18 are commonly found in cyanobacterial natural products.¹³ In principle, these could be generated by dedicated polyketide synthase (PKS) assembly line enzymes or by acyl-groups recruited from primary metabolism. Increasing studies on secondary metabolite biosynthetic gene clusters (BGCs) associated with cyanobacterial natural products, have made clear that most of these acyl moieties are either fully-derived from fatty acids or from PKS-mediated elongation of slightly shorter fatty acids.¹⁵ In fact, BGCs found in cyanobacterial genomes commonly encode fatty acid incorporating enzymes, most notably fatty acyl-AMP ligases (FAALs).¹⁴ The genomic contexts

of such fatty acid-incorporation genes often encode a rich diversity of biosynthetic enzymes, such as halogenases, desaturases, cytochrome P450s, methyltransferases, oxidoreductases, among others.^{14,16,17} In line with this, cyanobacterial natural products incorporating fatty acid-derived alkyl chains commonly exhibit rich decorations and structural features in such moieties.

Here, we present an account of unique aspects of fatty acid primary and secondary metabolism in cyanobacteria. We focus on the different ways by which these organisms incorporate fatty acids into their natural product scaffolds and the myriad of modifications that underline the structural diversity found in these lipidic natural products.

The uniqueness of cyanobacterial fatty acid metabolism

Cyanobacteria are photoautotrophic prokaryotes. They can fix atmospheric carbon and do not require any other external carbon source. Fixed carbon in the form of sugar recirculates through multiple pathways, including fatty acid biosynthesis. In addition, cyanobacteria can also internalize exogenous fatty acids. Smaller fatty acids diffuse freely through the membrane, while longer fatty acids are translocated through the action of acyl-acyl carrier protein (ACP) synthetase (Aas).¹⁸ This ATP-dependent enzyme generates acyl-ACPs from fatty acids internalized through its action or those that were internalized by diffusion. Fatty acyl-ACPs of different chain length can then be elongated through the regular fatty acid biosynthesis pathway.¹⁸ Aas enzymes carry out a reaction similar to FAALs and both are distinguishable from the related Fatty Acyl CoA Ligases (FACLs), despite the fact that all are members of the adenylate-forming enzyme superfamily.^{19,20} To our knowledge, Aas-encoding genes are not typically present in BGCs. Across the tree of life, fatty acyl-ACPs are used to generate membrane lipids of different sorts; in cyanobacteria these include several glycolipids that make up the extensive thylakoid membrane system²¹ (Fig. 1).

Many cyanobacteria also generate alkanes and alkenes from fatty acyl-ACPs, through the action of acyl-ACP reductase and aldehyde-deformylating oxygenase (Aar/Ado pathway).²² This route is unique to cyanobacteria and distributed throughout the phylum.^{22,23} 1-Alkenes can also be generated in cyanobacteria from fatty acyl-ACPs through an alternative pathway, the olefin synthase (Ols).^{24,25} Hydrocarbon production has interest for biotechnological purposes and these unique cyanobacterial pathways have been studied extensively under this scope.²⁶

However, perhaps the most striking feature of cyanobacterial fatty acid metabolism is their apparent lack of a beta-oxidation pathway. Beta-oxidative enzymes have not been reported from cyanobacteria.^{14,27,28} In a recent study from our group,¹⁴ it was not possible to find in cyanobacteria the full set of beta-oxidative genes from *E. coli*; in most cyanobacterial genomes, the majority of these functions were lacking altogether. The reason behind the absence of this fundamental

Fig. 1 Overview of fatty acid metabolism in cyanobacteria leading to lipid biosynthesis. Highlighted are the incorporation of exogenous fatty acids and the *de novo* biosynthesis of fatty acids from acetyl-CoA. ACP – acyl carrier protein; Aas – acyl-ACP synthetase; FAS – fatty acid synthesis pathway; G3P – glyceraldehyde 3-phosphate.

degradative pathway is unclear, but the widespread absence of pathway orthologs suggests that it is deep-rooted in cyanobacterial history.

Overall, the ability of cyanobacteria to generate a replenishing pool of fatty-acid biosynthesis units from photosynthesis-fixed carbon, to acquire fatty acids exogenously, coupled with

the absence of beta-oxidation, has likely shaped their secondary metabolism. In particular, the peculiarities of cyanobacterial fatty acid metabolism, notably the apparent lack of canonical degradation for energy, could explain why fatty acyl moieties are so common in cyanobacterial natural product scaffolds (Scheme 1).

Incorporation of fatty acids into cyanobacterial secondary metabolites

Fatty acids can be recruited to secondary metabolite biosynthesis by a variety of enzymes.¹⁴ Genes encoding these functions are often found in BGCs, allowing for the straightforward

Scheme 1 Selected cyanobacterial natural products containing fatty acid residues.

prediction of fatty acid incorporation. Often, transfer of a fatty acid onto a secondary metabolite biosynthetic pathway-specific ACP initiates biosynthesis. However, in other cases, fatty acid incorporation events can occur at later biosynthetic steps and may not even require a cognate ACP, instead using primary metabolism thioesters (which in cyanobacteria have invariably been found to be of the fatty acyl-ACP type instead of fatty acyl-CoA thioesters, further supporting absence of beta-oxidation in these organisms). In cyanobacteria, FAALs are the most commonly found fatty acid incorporating enzymes encoded in secondary metabolite BGCs.^{14,15} Lipoyl transferases and GNAT (Gcn5-related-*N*-acetyltransferase)-family enzymes are also capable of decorating natural product scaffolds or their biosynthetic precursors with fatty acyl moieties, while BrtB catalyzes the incorporation of non-activated fatty acid carboxylates^{29–31} Dialkylresorcinol/pyrone-forming enzymes and certain type III PKSs are proposed to recruit fatty acyl-ACP thioesters or their derivatives from primary metabolism and commit them to a specific secondary metabolite pathway.¹⁷ Starter C-domains can also be found in cyanobacterial BGCs³² and have been shown in other bacteria to *N*-acylate amino acids with beta-hydroxy fatty acyl groups³³ (Fig. 2).

Fatty acyl AMP ligases (FAALs)

FAALs are widespread in cyanobacterial genomes, with an average of over one homolog per publicly available genome.¹⁴ These are members of the acyl-adenylating enzyme superfamily and activate fatty acids by generating an acyladenylate (acyl-AMP) intermediate.³⁴ FAALs then acylate ACPs using the activated acyl-AMPs as substrates.³⁴ At this stage, the fatty acid residue is committed to a secondary metabolite biosynthesis pathway, as the ACP interacts with downstream enzymatic machinery. FAALs bear structural resemblance to FACLs, which acylate CoA instead of an ACP and are members of the same superfamily.²⁰ It has recently been shown that FAALs contain a non-functional CoA-binding pocket and use an alternative pocket to enable discrimination between *holo*-ACP and CoA and proceed with *holo*-ACP acylation.²⁰ The ACP-tethered fatty acyl moiety can then be further modified by the action of polyketide synthases (PKSs) or other ketosynthases (KSs), non-ribosomal peptide synthetases (NRPSs), all of which make use of carrier-protein thioester enzymatic logic. The cylindrocyclophanes (*e.g.* cylindrocyclophane **1**), nocuolin A (**2**), 1-alkenes (*e.g.* **3**) and a wide range of lipopeptides (*e.g.* hapalysin A, **4**) are examples of cyanobacterial natural products whose biosynthesis involves FAAL-mediated activation and incorporation of fatty acids.^{15,24,35–37} FAALs can be found in cyanobacterial genomes as single domain enzymes, with their partner ACP as FAAL-ACP didomain proteins, or integrated in multidomain megaenzymes.

Usually, cyanobacterial FAALs are responsible for the incorporation of a single fatty acid residue into each secondary metabolite end product. The resulting acyl-ACP moiety can then be elongated by PKS modules before further modification, which can include interfacing with NRPS modules (as in the biosynthesis of hapalosins³⁷ – *e.g.* **4** – or desmamides³⁸ – *e.g.*

Fig. 2 Biosynthetic strategies used by cyanobacteria to recruit and incorporate fatty acid residues into natural products. PKS – polyketide synthase; KS – ketosynthase domain.

desmamide A, **5**) to generate lipopeptides¹⁵ or a type III PKS to generate alkylresorcinols such as **1**.³⁵ It has been proposed that a FAAL-generated acyl-ACP interfaces directly with a starter C-domain (NRPS biosynthesis) to generate the hassallidins

(*e.g.* hassallidin A, **6**, see section below on starter C-domains).³² In the biosynthesis of the chlorosphaerolactylates (*e.g.* chlorosphaerolactylate A, **7**), a non-elongating PKS is predicted to shuttle the acyl chain to a depsipeptide synthetase (NRPS-like) module.³⁹ In contrast with these single-incorporation examples, we have recently shown that in the biosynthesis of the cyanobacterial 1,2,3-oxadiazine nocuolin A (**2**), a single FAAL – NocH – activates two different fatty acids (hexanoic and octanoic acids).³⁶ The two acyl-ACPs are then used by the KS NocG to generate a beta-keto acid featuring a linear 13-carbon chain.³⁶

BGCs that encode FAALs usually code for enzymes that modify and decorate acyl chains, including halogenases, cytochrome P450s, desaturases and other.^{16,40–43} Such modifications can influence the biological activity of the resulting natural product *e.g.*⁴⁴

Acyl(lipoyl) transferases

Malyngamides (*e.g.* malyngamide I, **8**)⁴⁵ are a large group of highly modified marine-derived cyanobacterial lipids. Bioinformatics analysis of their putative BGCs in the genus *Okeania* indicated the presence, in each BGC, of a gene encoding a lipoyl transferase of the lipoate-protein ligase A (LplA) superfamily.²⁹ The encoded enzyme – MgcA – is proposed to transfer an octanoyl moiety from octanoyl-ACP (from fatty acid biosynthesis) directly onto the KS domain of the ensuing PKS module, which would enable further elongation and processing through canonical PKS/NRPS to generate the final malyngamides.²⁹

Homologs of this enzyme were found in cyanobacteria and heterotrophic bacteria, including the *Bacillus subtilis* LipM, involved in *N*-acylation of protein lipoyl domains. These were not found in secondary metabolite biosynthesis genomic contexts. Thus, the authors propose that MgcA represents an example of neofunctionalization of LipM to serve a role in the biosynthesis of natural products.²⁹

Dialkylresorcinol/pyrone-forming enzymes

Dialkylresorcinol (DAR) biosynthesis from the head-to-head condensation of two fatty acid-derived precursors was characterized by Bode and co-workers.⁴⁶ The authors showed that DarB, a member of a phylogenetically congruent clade of widely distributed KSs generated carboxy-cyclohexanediones in *Chitinophaga pinensis*. These were proposed to be oxidized to resorcinols through the action of the oxidoreductase DarA that was found adjacent to the KSs in DAR-producing bacteria. This initial report indicated the presence of such two-gene cassettes in cyanobacterial BGCs.⁴⁶

The discovery of the bartolosides (*e.g.*, bartoloside B, **9**)⁴⁷ cyanobacterial glycosylated and halogenated DARs, paved the way for the study of BrtD, the DarB homolog encoded in the bartoloside-producing *Synechocystis salina* LEGE 06155. BrtD was shown to form a carboxy-cyclohexanedione from 2-octadecenoyl- and 3-oxo-hexadecenoyl-ACP thioesters. In the same study, BrtC (DarA homolog) was shown to be an aromatase generating the DAR backbone of the bartolosides.⁴⁷

DarB/DarA homologs are found in several orphan cyanobacterial BGCs of diverse architecture, suggesting that additional DAR classes are to be found in these organisms.¹⁷ Furthermore, in several BGCs, DarB homologs are also found in the absence of a DarA partner.¹⁷ In this case, it is unclear whether the final products contain cyclohexanedione moieties.⁴⁶

DarB and BrtD recruit fatty acid-derived thioesters from primary metabolism. However, DarB recruits both short and long-chain fatty acids to generate DARs,⁴⁶ while BrtD generates much longer DARs by recruiting, for example, C₁₆ and C₁₈ fatty acid derivatives in the biosynthesis of **9**.⁴⁷ Therefore, while it could be expected that the presence of DarB homologs in a BGC results in fatty acid-derivative recruitment, the structural basis and sequence determinants for selectivity are unclear at this stage. This hinders structural predictions from the bioinformatics analysis of such BGCs.

Type III PKSs

Bacterial type III PKSs perform both extension and cyclization of a variety of substrates.⁴⁸ The structures generated by these enzymes include quinones, pyrones, phloroglucinols and resorcinols.⁴⁸ In cyanobacteria, only two families of type III PKS products have been reported so far (cylindrocyclophanes such as 1/cylindrofridins such as **10** and hierridins, *e.g.* **11**),^{17,35,49,50} both involving generation of alkylresorcinol products. This is in contrast with an estimated prevalence of these genes in ~17% of cyanobacterial genomes.⁵¹ There is also considerable phylogenetic diversity associated with cyanobacterial type III PKSs, including homologs that clade with characterized alkylpyrone-generating type III PKSs from heterotrophic bacteria.^{17,51}

In cylindrocyclophane/cylindrofridin biosynthesis, a dedicated FAAL activates and loads decanoic acid onto a pathway-specific ACP. This carrier protein-tethered fatty acyl thioester is then elongated by type I PKS machinery before further elongation and cyclization into an alkylresorcinol by the type III PKS enzyme.^{35,49,52}

In contrast, the hierridin BGC (*hid*) does not contain an ACP and instead we have proposed⁵⁰ that hexadecenoyl-ACP from fatty acid biosynthesis is recruited by the type III PKS HidC into the hierridin pathway. This substrate would be extended by three acetate units (from malonyl-CoA) before cyclization into an alkylresorcinol by the same enzyme and further modification by other pathway enzymes. A large number of BGCs that are similar to *hid* and do not contain an ACP in their genomic contexts are found distributed in free-living, planktonic cyanobacteria with smaller genomes and are expected to generate similar alkylresorcinols.^{50,51}

Likewise, type III PKS-encoding BGCs in cyanobacteria that are expected to generate alkylpyrones, are also lacking a dedicated ACP and likely also recruit fatty acyl-ACP substrates from primary metabolism.^{17,51}

Starter C-domains

In NRPS biosynthesis, canonical C-domains perform the N-to-C condensation of an amino acyl or peptidyl-carrier protein (or domain) donor and an amino acyl-carrier protein (or domain)

acceptor.¹⁰ Other C-domain types can perform additional functions, including cyclization and dehydration, epimerization and ester bond formation.⁵³ Starter C-domains are yet another subclass of C-domains that generate lipopeptides by performing a condensation reaction using a fatty acyl thioester acceptor instead of an amino acyl-carrier protein thioester.³³ These domains are usually in the first NRPS module acting in the biosynthesis of such lipopeptides. Both CoA and ACP fatty-acyl thioesters have been shown to *N*-acylate the amino acyl-carrier protein in the first NRPS module.²

In cyanobacteria, the involvement of a starter C-domain in the biosynthesis of the lipoglycopeptides hassallidins (*e.g.* **6**) has been proposed to follow the action of the fatty acid-recruiting FAAL HasG, which is part of the hassallidins BGC (*has*).³² However, in the biosynthesis of the anabaenolysins (*e.g.* anabaenolysin A, **12**), antifungal lipopeptides produced by *Anabaena* spp., a starter C-domain is expected to perform the *N*-acylation of an aspartyl-carrier protein thioester from the first NRPS module (AblA).⁴⁰ The *abl* BGC does not appear to encode a fatty acid activating enzyme, but the initial NRPS contains an ACP domain which is expected to be loaded with the acylating fatty acid and, therefore, be the acceptor substrate of the reaction of the starter C-domain.⁴⁰

GNATs

A recent report³¹ has expanded the arsenal of fatty acid-incorporating enzymes in natural products biosynthesis to include enzymes of the GNAT superfamily. GNAT enzymes commonly participate in different biological processes, through acylation (usually acetylation, but sometimes other groups) of different substrates such as proteins or sugar residues.⁵⁴ Acyl-CoAs are the reported source of the transferred acyl groups, and while *N*-acylation is by far the most commonly reported activity for these enzymes, *O*-acylation has also been observed⁵⁴ and in the biosynthesis of the cyanobacterial natural product curacin, *S*-acetylation was attributed to a GNAT domain.⁵⁵

A GNAT enzyme from a streptomycete was also shown to transfer a PKS-derived long acyl chain (from acyl-ACP) to the N-terminus of a peptidic intermediate originating from ribosomally synthesized and post-translationally modified peptide (RiPP) machinery.⁵⁶ In their report, Hubrich *et al.*³¹ show another way by which RiPP biosynthetic pathways can lead to lipopeptides. Specifically, the authors have shown that certain GNAT enzymes, part of (RiPP) BGCs (KspN from a cyanobacterium and PhaN from an alphaproteobacterium), can selectively *N*-acylate lysine or ornithine side chains in peptide scaffolds. It was proposed that the dodecanoic acid residue found in the cyanobacterial pathway end-product (kamptornamide, **13**) is derived from the primary metabolite pool (*i.e.*, an acyl-CoA or -ACP species).³¹ Because RiPP pathways are amenable to combinational biosynthesis through simple genetic manipulation, a variety of lipopeptide structures can now in principle be engineered in a straightforward manner.³¹

BrkB

The above-mentioned fatty acid incorporation reactions make use of thioester chemistry, resulting in fatty acylation. Our group has

recently uncovered a new type of fatty acid incorporation into secondary metabolites that, instead, uses the fatty carboxylate as a nucleophile and a secondary alkyl chloride as the electrophile. This reaction is carried out by BrtB, an enzyme encoded in the bartoloside BGC (*brt*).³⁰ BrtB catalyzes the esterification of fatty acids onto the alkyl chains of the bartolosides, generating bartoloside esters such as metabolite **14**. It shows remarkable promiscuity towards the fatty acid nucleophile, being capable of esterifying short-, medium- and long-chain fatty acids.³⁰ The only characterized homolog of BrtB, CylK is also capable of transferring a lipidic substructure to alkyl halides, namely an alkylresorcinol, in cylindrocyclophane biosynthesis.⁵²

Modification of fatty acyl moieties in cyanobacterial natural products

Quite often, fatty acid-derived moieties are modified during the biosynthesis of cyanobacterial secondary metabolites. These modifications occur with high selectivity and in positions that can be distant from the acyl carbonyl (Scheme 2 and 3) and influence biological activity *e.g.*⁴⁴

Unsaturation

Desaturases are common in a range of organisms and generate unsaturated versions of fatty acyl moieties, generating alkenes or alkynes.^{9,57,58} For example, acyl-lipid desaturases are well-known regioselective enzymes found in cyanobacteria and other organisms that act on the acyl chains of membrane lipids, and therefore modulate membrane fluidity in response to changing environmental conditions.⁵⁹ Many desaturases act on cyanobacterial secondary metabolite biosynthesis as well. Microcarbonin A (**15**) features a conjugated diyne in one of the chains of its dialkylresorcinol core.⁶⁰ Its putative BGC contains two desaturases.^{17,46} Metabolites such as **12** contain long fatty acyl moieties (C₁₈-derived) that contain various degrees of unsaturation and at different positions, probably through the action of the desaturase AblC.⁴⁰ Additional examples of cyanobacterial metabolites with long alkyl chains featuring unsaturations compatible with the action of a desaturase include fischerellins A (**16**)⁶¹ and B (**17**)⁶² and nostocycline (**18**).⁶³

Terminal alkynes and alkenes can also be generated in fatty acyl moieties through the action of desaturases.⁵⁸ This is the case of the well-studied biosynthesis of the terminal alkyne moiety in the jamaicamides (*e.g.* jamaicamide B, **19**),^{64,65} in which the desaturase JamB acts sequentially on hexanoyl-JamC(ACP) to generate first 1-hexenoyl-JamC and then 1-hexenoyl-ACP (Fig. 3). Terminal olefins can also be generated by the Ols pathway, as mentioned above, which employs an FAAL and type I PKS machinery to elongate/decarboxylate a fatty acyl-ACP substrate.^{24,25} Marine cyanobacterial cyclic lipopeptides of mixed PKS/NRPS origin, belonging to the so-called kululide superfamily of natural products (*e.g.* viequeamide A, **20**),⁶⁶ typically feature a fatty acid-derived residue. This can be saturated, a terminal alkene or a terminal alkyne and the three versions are usually co-produced.⁶⁶ The biosynthesis of the

Scheme 2 Examples of cyanobacterial natural products that contain modified fatty acid residues.

unsaturated versions in this superfamily of cyclic peptides expected to occur in a similar fashion to the jamaicamides.⁶⁷ The same has been proposed for the terminal alkyne moieties of the linear lipopeptides vatiamides.⁶⁸ A cyanobacterial allenic fatty acid – puna’auic acid (**21**) – has been reported from a marine cyanobacterium. Its biosynthesis is proposed to involve an enyne precursor, which would then be converted to a propargyl epoxide and reduced to the allene.⁶⁹

Halogenation

Cyanobacteria are rich in enzymatic chemistry resulting in halogenated natural products.^{16,70,71} Different classes of halogenating enzymes are encoded in cyanobacterial BGCs, namely flavin-dependent, nonheme iron/2-oxo-glutarate (2OG)-dependent and dimetal carboxylate halogenases.^{16,71} From these, dimetal carboxylate and nonheme iron/2OG-dependent halogenases have been shown to act on alkyl moieties.¹⁶ Of particular interest for biocatalysis are regio- and stereoselective halogenations on terminal or mid-chain unactivated sp³-hybridized carbons. These are observed commonly in a number of cyanobacterial metabolites containing fatty acid-derived alkyl moieties, like, for example, the columbamides (*e.g.* columbamide A, **22**),⁷² bartolosides (*e.g.* **9**),⁴⁷ microginins (*e.g.* microginin 739, **23**),^{43,73} cylindrocyclophanes/cylindrofridins (*e.g.* **1/10**),^{17,49,74} among others. In most such

metabolites, chlorine or bromine atom installation can be linked to dimetal carboxylate halogenases, based on BGC annotation.¹⁶ That is the case of CylC (Fig. 3), which acts during the biosynthesis of **1/10** and related metabolites and has been characterized biochemically.⁵² But, for example the generation of the 5,5-dichloro group in hexanoyl-ACP during hectochlorin (**24**) biosynthesis, is attributed to the nonheme iron/2OG-dependent halogenase HctB.^{75,76} Mid-chain *gem*-dichlorination has been observed not only in hectochlorin and related metabolites but also in a bartoloside – suggesting that the dimetal carboxylate halogenase BrtJ can also generate this group.⁷⁷ *Gem*-dichlorinations have been most often reported in terminal positions (*i.e.* dichloromethyl group) in marine and freshwater cyanobacterial metabolites (*e.g.* microginins, columbamides, cylindrofridins) associated with BGCs encoding dimetal carboxylate halogenases.¹⁶ (Di)halovinylidenes are additional structural motifs associated with fatty acid halogenation. These rare moieties can be seen in the taveuniamides (*e.g.* taveuniamide E, **25**)⁷⁸ and caracolamide A (**26**)⁷⁹ and in sponge-derived azirines *e.g.*⁸⁰ that have been recently linked to a cyanobacterial biogenetic origin.⁸¹ Recently reported cyanobacterial metabolites such as the aranazoles (*e.g.* aranazole C, **27**)⁴¹ or fischerazoles (*e.g.* fischerazole A, **28**)⁴² illustrate the rich regioselective decoration of fatty acid-derived alkyl moieties with halogens.

Scheme 3 Examples of cyanobacterial natural products containing modified fatty acid residues.

Fig. 3 Examples of biochemically-characterized fatty acyl modification reactions in cyanobacterial secondary metabolite biosynthesis.

This is particularly remarkable in the biosynthesis of the aranazoles, where six halogenated positions are likely generated by the six nonheme iron/2OG-dependent halogenases encoded in the putative aranazole BGC (*arz*).⁴¹

Oxygenation

Certain cyanobacterial lipopeptides feature oxygenation in their fatty-acid derived moieties. For example, the related

puwainaphycins and minutissamides (e.g. puwainaphycin A, **29** and minutissamide D, **30**)^{82,83} contain mid-chain hydroxy and keto groups, which are likely attributable to an oxygenation event catalyzed by the cytochrome P450 monooxygenase PuwJ.^{44,84}

Epoxide groups are common modifications in marine lipids, such as in the algal oxylipins.⁸⁵ Still, in cyanobacteria, this is a rare moiety in fatty acid-derived alkyl chains, and, to our knowledge, has been reported only in aranazole D (**31**).⁴¹ Gloeolactone (**32**)⁸⁶ also features an epoxide but it is unclear if this compound is fully derived from a fatty acid or that it is a fatty acid-polyketide hybrid. While Piel and co-workers, who reported the *arz* BGC, have not speculated on the origin of the epoxide,⁴¹ it encodes two putative P450 oxygenases and one putative Rieske oxygenase, which could be linked to this structural modification.

Additional modifications

Apart from these more commonly observed modifications, a number of additional transformations involving fatty acyl moieties have been reported. Grenadadiene (**33**) and grenadamide (**34**)⁸⁷ feature a dodecanoic acid-derived cyclopropanated acyl moiety, likely of similar biosynthetic nature that the cyanobacterial lynchyoic acid (**35**).⁸⁸ These modifications are well-known from *Mycobacterium tuberculosis* cell-wall mycolic acids, in which case they are generated through olefin methylation and

cyclization by a specific type of SAM-dependent enzyme (cyclopropane synthase).^{89,90}

Metabolites with unusual cyclizations that appear associated to fatty acid-derived moieties include **18**, **32** and **2**. In the case of **18**, the cyclization between the resorcinol and the mid-chain position is likely generated by an intramolecular version of the reaction catalyzed by CylK in cylindrocyclophane biosynthesis, which should involve a cryptic halogenation.¹⁷ The biosynthesis of **32** has not been proposed but it is plausible that either a C₁₈ fatty acid generates the entire carbon skeleton or that a C₁₀ fatty acyl precursor is elongated by PKS machinery before thioesterase-catalyzed cyclization with the C-1-derived alcohol acting as a nucleophile. During the biosynthesis of **2**, the 13-carbon linear chain is further modified to generate the unusual 1,2,3-oxadiazine moiety, whose biosynthesis remains to be elucidated.³⁶

In most natural products, fatty acyl moieties tend to be found as esters or amides. However, this is not the case of the anticancer lead compound largazole (**36**), a cyanobacterial lipopeptide whose lipid tail features an unusual decanoyl thioester moiety.⁹¹

Capturing natural products diversity associated with fatty acids

A faster access to lipidic natural products has the potential to accelerate the discovery of drug-like metabolites⁸ and reveal enzymes that can selectively modify alkyl moieties and thus be of interest for biocatalytic applications.

Precursor supplementation

In previous work, we considered that the diversity of functions associated with fatty acid-incorporating enzymes encoded in cyanobacterial BGCs could be regarded as an opportunity to discover unusual natural product structures. Hence, we developed a metabolomics-based method that allowed us to detect such compounds, some of which we have reported.^{14,42} The method involves supplementation of cyanobacterial cultures with perdeuterated fatty acids, namely d₁₁-hexanoic acid. The deuterons eventually get incorporated into lipids, including natural products, and the label is not scrambled due to the absence of fatty acid degradation (Fig. 4(A)). Mass spectrometry-based comparative metabolomics is then used to detect mass shifts from a non-supplemented control. As anticipated, the discovered compounds contain multiple decorations and hide unusual chemistry. In particular, the nocuolactylates (*e.g.* nocuolactylate A, **37**)¹⁴ and the fischerazoles (*e.g.* **28**)⁴² are highly unusual fatty acid-incorporating structures that have been uncovered using this strategy.

Heterologous expression of orphan BGCs

Heterologous expression of cyanobacterial BGCs has not progressed as fast as for other groups of chemically rich bacteria (most notably actinobacteria *e.g.*⁹²). In recent years, however, considerable progress has been made and several BGCs found

Fig. 4 Strategies for the discovery of cyanobacterial natural products incorporating fatty acid residues. (A) stable isotope-labelled fatty acid supplementation of cyanobacteria cultures leads to incorporation of labelled fatty acid residues into lipids (including natural products), which can then be detected by mass spectrometry. (B) expression of BGCs encoding fatty acid-incorporating or -recruiting enzymes in a heterologous host can reveal new natural products that feature fatty acid residues.

in the genomes of cyanobacteria have been successfully expressed in heterologous hosts, cyanobacterial or not (Fig. 4(B)).⁹³ Hapalosisin A, a product of hybrid PKS/NRPS biosynthesis, was successfully expressed in *E. coli* using Direct Pathway Cloning Combined with Sequence- and Ligation-Independent Cloning (DiPaC-SLIC).³⁷ Octanoic acid is incorporated into the hapalosisins through the action of a FAAL enzyme.^{14,37} Another FAAL-containing BGC – *mic*, associated with the microginin family of compounds – was again successfully expressed in *E. coli* using DiPaC-SLIC to generate natural and non-natural variants of these metabolites.⁴³ The dimetal carboxylate halogenase that generates the dichloromethyl terminus in several microginins (*e.g.* **23**) was functional in *E. coli*

and appeared to prefer bromine to generate dibromomethyl microginin analogs.⁴³ Using the cyanobacterium *Nostoc* sp. PCC 7120 as a heterologous host, a range of halogenated columbamides (e.g. 22), including non-natural analogues, were produced in yields comparable to the natural producer (*Moorena bouillonii* PNG5-198).⁹⁴

Conclusions

The ecophysiological uniqueness of cyanobacteria has shaped their natural products biochemistry. The availability of fatty acids in cyanobacterial cells, resulting from photosynthetic carbon fixation, apparently unabated by a catabolic pathway such as beta-oxidation, has turned these into important substrates for several biosynthetic pathways. In particular, natural products biosynthesis in cyanobacteria makes common use of fatty acid substrates and modifies them to a great extent using a rich combination of enzymes. Over the years, the discovery of cyanobacterial natural products that feature fatty acid residues and the study of their biosynthesis have revealed multiple instances of complex and intricate biochemical events. Still, the phylum Cyanobacteria remains to be extensively explored for their natural products and genome and metagenome data associated with these organisms contains a wealth of BGCs that are not associated with known natural products. Many of such BGCs can be predicted to incorporate fatty acid residues. Therefore, there are ample opportunities for accessing new chemical space within these organisms but also for finding interesting enzymatic chemistries that act selectively on barren alkyl chains. In addition, a better understanding of fatty acid incorporating enzymes, in particular how selectivity as to chain length is achieved, will lead to better predictions of natural products structures from sequence data, something that is currently lacking.⁹⁵
