Abstract

View Article Online
DOI: 10.1039/D5TA06611E

Among all the alternative battery systems beyond lithium-ion batteries (LIBs), all-solid-state fluoride ion batteries (ASSFIBs) are particularly promising due to their high theoretical energy density, thermal stability, and recent advancements in room-temperature superionic solid electrolytes and intercalation-type electrodes. However, their practical application is hindered by poor cycling stability and limited rate capability, largely attributed to unfavored kinetics and interfacial degradation, especially in conversion-type cathodes. Previous studies have shown that the application of stack pressure can significantly improve the cell's cycling stability. To reveal the underlying mechanism, this study systematically investigates the impact of stack pressure on the electrochemical performance of ASSFIBs using $\text{BiF}_3|\text{BaSnF}_4|\text{Sn}$ cells. Among the tested conditions, the best enhancement of cycling stability and rate performance were demonstrated under 180 MPa. Furthermore, ex-situ diffraction analysis revealed pressure-dependent phase evolution and oxygen-related interfacial degradation (i.e., BiOF or $\text{BiO}_{0.1}\text{F}_{2.8}$ formation) in the BiF_3 cathode during the first cycle. Through in-situ electrochemical impedance spectroscopy combined with distribution of relaxation times analysis we identified charge transfer and F^- diffusion as the dominant state-of-charge dependent kinetic limitations, with strong correlation to phase transitions within the BiF_3 cathode composite. These findings emphasize the critical role of stack pressure in mitigating interfacial degradation and optimizing ion transport, providing valuable insights for the design and operation of high-performance ASSFIBs.

All solid-state fluoride ion batteries; Conversion-based cathode; Stack pressure; Impedance Spectroscopy; Distribution of relaxation times

1 Introduction

The widespread adoption of Li-ion batteries (LIBs) in transportation devices and renewable energy storage systems has reshaped society over the last decades and promises a sustainable future. However, the flammability of liquid electrolytes and the high cost of critical raw materials for LIBs have motivated a technological shift towards all-solid-state batteries (ASSBs) and systems employing alternative shuttle ions, such as Na^+ , Mg^{2+} , Cl^- and F^- , to meet ever-increasing demands of large-scale energy storage. Recently, all solid-state fluoride-ion batteries (ASSFIBs) are becoming more competitive due to their high theoretical energy density up to $\sim 5000 \text{ Wh L}^{-1}$ using metal fluorides as electrodes^{1, 2}, thermal stability, as well as progress in developing superionic solid electrolytes at room-temperature and intercalation-based electrode materials such as La_2CoO_4 , La_2NiO_4 , $\text{La}_{2-x}\text{Sr}_x\text{MnO}_4$ and their derivatives³⁻⁷.

However, in practical application, the potential of ASSFIBs is hindered by poor cycling stability, limited rate capability, unfavored diffusion and/or reaction kinetics, and interfacial degradation. These limitations can be broadly attributed to two key processes: mechanical inter-particle contact loss (suddenly or progressively) and the chemical decomposition at the interfaces^{8, 9}. Unlike liquid electrolyte systems, where mechanical accommodation occurs more easily, all-solid-state batteries (ASSBs) are subjected to mechanical constraints, from fabrication to operation. Even minor volume fluctuations in active materials can bring substantial internal stress into the system¹⁰. In ASSFIBs, particularly for conversion-based cathode materials, the reduction of metal fluorides (can be described by $\text{MF}_y + y\text{e}^- \rightarrow \text{M} + y\text{F}^-$) accompanied by large volumetric changes ($\Delta V \approx 30\text{-}70\%$), will lead to severe delamination between particles within the composite. This can result in poor electronic/ionic percolation, increased overpotential, and ultimately, rapid capacity fading. Furthermore, interface instability between the electrode and solid electrolyte appears to dominate the cell performance in ASSBs, even more than in conventional lithium-ion batteries (LIBs), since the undesirable reaction products cannot dissolve and diffuse in the solid electrolyte¹¹.

63 To overcome these challenges, many strategies have been explored, including the
64 optimization of electrode composite, and interfacial engineering¹²⁻¹⁷. Among them, applying
65 stack pressure has shown significant benefits by mitigating the inter-particle contact loss and
66 partially stabilizing interfacial reactions¹⁸⁻²³. The effects of stack pressure appear to be system-
67 specific, depending on the chemical & mechanical properties of the electrode solid electrolyte
68 interface. In all-solid-state lithium-ion batteries (ASSLIBs), numerous studies have shown the
69 pressure-dependent improvement originates from various mechanisms. For example, the ionic
70 conductivity of Li_3InCl_6 increases from 0.35 to 0.52 mS cm^{-1} when pressure is raised from 2 to
71 10 MPa at 30 °C, which in turn enhances the utilization of cathode active materials such as
72 single-crystal $\text{LiNi}_{0.83}\text{Mn}_{0.06}\text{Co}_{0.11}\text{O}_2$, leading to 93 % capacity retention after 50 cycles at
73 10 MPa, compared to 65 % at 2 MPa²¹. Many works have also reported that the intrinsic
74 volume change of electrode active materials determines the critical stack pressure to maintain
75 an intimate and effective interface to achieve sustained cycling. For instance, Silicon anodes
76 (up to 300 % volume expansion upon lithiation) require a stack pressure of 50-120 MPa^{24, 25},
77 while Nb_2O_5 with 4 % expansion, only needs a minimum stack pressure of 2 MPa to reach
78 capacity retention above 96 % over 30 cycles²². In contrast, zero-strain cathode like $\text{Li}_4\text{Ti}_5\text{O}_{12}$
79 (LTO) can maintain coulombic efficiency above 99 % under a minimal pressure of 0.1 MPa²².

80 Our previous study extensively investigated the pressure-dependent conductivity of various
81 solid electrolytes for ASSLIBs and demonstrated significant improvements in electrochemical
82 performance for conversion-based and intercalation-based electrodes under applied stack
83 pressure¹⁸. However, the mechanism underlying the effects of stacking pressure on ASSLIBs
84 remains unexplored. In solid-state batteries, electrode-electrolyte interfacial degradation has
85 been studied using techniques such as XPS, TOF-SIMS, and TEM. Alongside these methods,
86 electrochemical impedance spectroscopy (EIS) has significant advantages as a non-
87 destructive tool for probing interfacial kinetics under operando conditions. While equivalent
88 circuit modelling (ECM) of impedance spectra has traditionally been used for data
89 interpretation, its application in ASSBs is limited by overlapping impedance features with

similar time constants and difficulty in distinguishing electrode contributions. In recent years, distribution of relaxation times (DRT) analysis has been extensively applied in LIBs research²⁶⁻³⁰, and its application is becoming increasingly important in ASSBs. By converting impedance data into the time domain without circuit assumptions, DRT can reveal distinct relaxation processes, such as charge transfer, ion diffusion, and interphase formation, with high resolution, enabling clearer interpretation of complex interfacial phenomena.

In this work, we report on the pressure-dependent cell performance of a BiF₃ cathode composite. The first-cycle performance under varying pressure is investigated, in addition to determining cycling stability and C-rate capability under high stacking pressure. Furthermore, operando X-ray diffraction (XRD) and ex-situ XRD analysis are used to investigate the phase evolution of the BiF₃ cathode in BiF₃|BaSnF₄|Sn cells. In addition, in-situ EIS with DRT analysis is employed to study the state-of-charge (SOC) and pressure dependence of different polarization processes, including charge transfer and ion diffusion. The results reveal the complex multi-scale effects of stack pressure, from crystalline phases formation and O²⁻/F⁻ diffusion to macroscopic interfacial behavior, which then collectively influence the overall cell performance.

2 Experimental

2.1 Material synthesis

Barium fluoride (BaF₂) (99.99 %) and tin fluoride (SnF₂) (99 %) from Sigma Aldrich were used for synthesizing electrolyte BaSnF₄ by mechanical milling and post soft annealing. All starting materials were dried in a vacuum furnace inside an argon-filled glovebox to remove any absorbed moisture. Stoichiometric amounts (~3 g in total) were sealed in a ZrO₂ milling vial (50 mL) with ZrO₂ milling balls (5 mm diameter, ball-to-powder ratio of 17:1) under argon atmosphere in the glovebox and milled at 600 rpm for 4 hrs using a Retsch Planetary Ball Mill PM100. After ball milling, the powder mixture was annealed at 300 °C for 2 hrs under dynamic vacuum (10⁻² mbar) using a Büchi Glass Oven B-585. The mechanical milling and the

annealing process were repeated three times to enhance the doping process. Bismuth trifluoride (BiF_3) (99 %), Sn nanopowder (>99 %, <150 nm particle size (SEM)) and carbon nanofibers (CNF) (>98 %) from Sigma Aldrich were used to prepare the BiF_3 cathode and Sn anode composites, as described by Reddy et al.³¹. The cathode composite consisted of 40 wt% BiF_3 , 50 wt% BaSnF_4 , and 10 wt% CNF, while the anode composite contained 50 wt% Sn, 40 wt% BaSnF_4 , and 10 wt% CNF. Again, BiF_3 and CNF were dried at 190 °C under dynamic vacuum for 24 hrs using the vacuum furnace before the synthesis process.

2.2 Cell assembly and Electrochemical measurements

Cell pellets were prepared in a three-layers configuration by uniaxial pressing anode composite, electrolyte, and cathode composite using a Specac Atlas 25T manual hydraulic press in an argon-filled glovebox (2 t for 90 s). The mass loadings of electrolyte, anode composite and cathode composite were 200 mg, 10 mg and 5 mg, respectively, i. e., the anode composite was used in excess as compared to the cathode composite. The galvanostatic cycling was performed at 100 °C in the potential range from 0.05 to 1 V (vs. Sn/SnF_2) with a current density of $20 \mu\text{A cm}^{-2}$ (unless specified otherwise) on potentiostats from Biologic Science Instruments (VSP or VMP-300 for cycling and VSP-300 for operando XRD measurements). The specific capacities were calculated based on the weight of active material in the cathode composite (BiF_3). For the C-rate capability test, a staircase increase of the C-rate (0.02C, 0.5C, 0.1C, 1C) was selected and conducted for three cycles each, after 15 consecutive cycles at 0.01C.

For galvanostatic cycling under different stack pressures, cells were assembled and tested directly in the customized hot-press setup¹⁸. The disc springs were used to minimize the force changes due to dynamic volume change of the pellet during cycling. Stack pressure variation between 20 and 450 MPa were studied due to the stable pressure range of the disc springs used. The chosen electrolyte was first filled in and compacted by hand. Afterwards the anode composite was hand-compacted on one side of the electrolyte and the cathode composite on the other side. The cells were compacted at 450 MPa for 90 s in a housing module made of

Al₂O₃ (inner diameter 7.5 mm, corresponding to a cell area of 0.441 cm²) which then sits inside a steel mantle for radial constraint of the alumina housing. A pair of cylindric hot working steel pins (AISI H11, 7.5 mm in diameter) were used as the current collector, which were aligned and electronically insulated by additional PTFE tubes. The entire hot-press setup was placed inside an argon-filled glovebox for operation under an inert atmosphere to avoid possible material degradations which can be induced by the presence of humidity and/or oxygen. Before cycling, the cell was heated up to the desired temperature and held for at least 4 hrs to reach thermal equilibrium. A pre-stack pressure which is slightly lower than the desired value was applied on the cell before heating, to minimize internal delamination due to thermal expansion, and the actual stack pressure after thermal equilibration was calculated from the recorded on-site force and adjusted accordingly. Cells cycled in typical high-temperature Swagelok type cells³¹ (~0.2 MPa) are referred to as non-pressure cells within this manuscript. To investigate the phase evolution of BiF₃ during charging, operando XRD measurements during galvanostatic cycling were conducted at 100 °C, and a Swagelok-type cell of compact design was used³², where the pressure applied to the cell was estimated to be less than 0.1 MPa. The detailed description of operando XRD measurement can be found in chapter 2.3.

To evaluate the SOC and pressure-dependent interfacial degradation of BiF₃ cathode composite, EIS was performed under various stack pressures using VSP or VMP-300, after 2 hrs of galvanostatic cycling at 40 μA cm⁻² and the following 2 hrs of rest (open-circuit voltage (OCV) monitoring). Impedance spectra were recorded at open circuit state using a signal amplitude of 10 mV in the frequency range of 1 MHz to 100 mHz. DRT analysis was performed using RelaxIS 3 from *rhd instruments*. The DRT transformation with Gaussian radial basis function (RBF)-based discretization was conducted to deconvolute the complex impedance data. The second derivative of the distribution function was used as the penalty item for all patterns in this work, with a shape factor value of 0.5 and regularization parameter $\lambda = 10^{-7}$. The obtained DRT patterns with multiple peaks were fitted using Gaussian functions to

determine the characteristic time constants and peak areas. More details are described in literature²⁸.

2.3 X-ray diffraction

A Rigaku SmartLab diffractometer with a Cu K $\alpha_{1,2}$ radiation (40 kV, 30-40 mA) and a HyPix-3000 detector was used to characterize the crystal structure of the synthesized electrolyte, cathode and anode composites as well as cell pellets after galvanostatic cycling in Bragg-Brentano geometry.

For ex-situ X-ray diffraction experiments, powder samples or cell pellets released from ceramic modules at different SOC were placed in low background airtight sample holders inside an argon-filled glovebox. X-ray diffraction (XRD) patterns were recorded at room temperature, with an incident slit size of 0.3°. A step size of 0.005° was applied in the 2 θ range from 10° to 80°, leading to a total measurement time of 2 h 35 min. Since the phase evolution of the cell investigated during discharge has been demonstrated in our previous study³², operando XRD patterns were recorded at 100 °C on a cell pellet (cathode side) at discharged state (pre-discharged to 0.05 V against Sn/SnF₂) while galvanostatic charging was performed in this work. The 2 θ range was limited to 21.5°-40.5° with a step size of 0.005° (a scan time of 26 min). To obtain sufficient time-resolved data allowing for both phase analysis and quantification, a loop measurement was programmed to record XRD patterns during the galvanostatic charge process, at 1 hr intervals. More details about the operando measurement can be found in our previous publication³².

Rietveld analysis of the diffraction data was performed using TOPAS V6³³, using a fundamental parameters approach as described in literature⁶, with the instrumental broadening being derived from a reference scan on a NIST standard of LaB₆ (660a). To refine the different crystal structures of BiF₃, Bi, and oxidefluorides, crystallographic information, as reported in literature³⁴⁻³⁷, was used without adjusting the atomic positions, but allowing for the refinement of lattice parameters. The structural model for the orthorhombic modification o'-BiF_{3-x} was derived as described in literature³². To account for angular dependent broadening effects from

crystallite size and micro strain in the individual phases, two Voigt functions were used. An identical thermal displacement parameter of all atoms of all phases was constrained to minimize quantification errors. Batch Rietveld analyses were performed on operando XRD patterns by a python script which repeat the fitting process with the pre-refined boundary values and constraints carefully set on parameters in Topas V6 software to the group of patterns.

3 Results and Discussions

3.1 Pressure effects on cell performance

3.1.1 Cell performance during the first cycle under various stack pressures

Figure 1 shows the relation between the first-cycle behavior of BiF_3 composite and stack pressures. The dQ/dV plots of the cells under various stack pressures during (dis)charge are summarized in Figure 1a), with detailed features within the selected voltage range demonstrated in Figure 1b-e). It can be seen that the peaks in the dQ/dV curves show strong changes with stack pressure. With an increase in stack pressure from 24 MPa to 221 MPa, the cell overpotential, represented by the difference between redox reaction plateaus during dis(charging), reduces by approximately 50 mV (marked by blue arrow in Figure 1b, d and e)). It is indicated by the peaks corresponding to reduction reaction plateaus in the dQ/dV plots, which shift toward higher values (Figure 1d and e), and the peaks corresponding to oxidation reaction plateaus, which shift to lower values (Figure 1b). However, upon further increasing the pressure to 410 MPa, the overpotential begins to rise again (marked by red arrow in Figure 1b, d and e). The corresponding specific capacities of all cells are plotted in Figure 1f, and the charge-to-discharge capacity ratio was calculated to evaluate the cell efficiency. Both discharge and charge capacity are enhanced with stack pressure up to 221 MPa, and decrease with further increasing the pressure, leading to a consistent increase in coulombic efficiency. This observed behavior in the cell overpotential and the (dis)charge capacity correlates well with the pressure-dependent ionic conductivity of the solid electrolyte BaSnF_4 . Figure 1g shows the total resistance (bulk and grain boundary contribution are not distinguishable

(representative EIS measurement is provided in Figure S 2) of the pure electrolyte (200 mg) under different pressure conditions obtained by electrochemical impedance measurement, between 14 to 450 MPa, which reflects directly the contribution of the electrolyte layer to the polarization process. The logarithm of the ionic conductivity of BaSnF₄ is plotted as a function of pressure as the inset, where the linear decrease in ionic conductivity of BaSnF₄ with pressure explained by the so-called activation volume of the electrolyte, i.e., the intrinsic ionic conduction properties of the electrolyte^{18, 38}. The increase in the electrolyte resistance at low-pressure range is attributed to loss of contact at the pellet interface with current collectors and within the pellet itself (crack formation due to the elastic recovery of the pellet). Furthermore, the DC polarization measurement of BaSnF₄ at 100 °C under varied pressure conditions lacks pressure dependency of its electronic conductivity (which is low in the order of 10⁻⁹ S cm⁻¹), which rules out an electronic contribution to the observed conductivity trend (Figure S 3). More details on the pressure effects on BaSnF₄ and other solid electrolytes in ASSFIBs are provided in our previous study¹⁸. In SSBs, ion conduction of solid electrolyte and, if applicable, through solid electrolyte interfaces (SEIs), are typically static and SOC-independent processes. Therefore, their contribution can be more easily identified³⁹. A similarly relationship was reported by Gao et al.²¹ in ASSLIBs, where a strong correlation between ionic conduction of electrolyte and the achievable cell capacity was demonstrated. Consistent with these findings, our results indicate that in ASSFIBs based on a BiF₃ cathode, the effect of stack pressure on cell capacity primarily arises from its influence on the pressure-dependent ionic conduction performance of electrolyte, which is reflected by shifts in redox reaction plateaus.

3.1.2 Cell performance under high stack pressure

To evaluate the long-term impact of stack pressure on the $\text{BiF}_3|\text{BaSnF}_4|\text{Sn}$ cell, galvanostatic cycling was conducted at 100 °C under a constant stack pressure of 180 MPa (selected based on the first-cycle cell performance in 3.1.1) using a current density of 20 $\mu\text{A cm}^{-2}$. Our previous study demonstrated that for sufficiently high charge cutoff potential, stack pressure can induce a second plateau around 1.1 V, which could be attributed to side reactions related to fluorination of stainless steel pin or CNF¹⁸. Therefore, in this work, a charge cutoff condition of 1 V was chosen to avoid undesired side reactions. Figure 2a and c) demonstrates the potential profile against capacity of the pressure cell and compares the corresponding coulombic efficiency (CE) and energy efficiency (EE) of both cells. The CE is determined by the ratio of the charge capacity to the discharge capacity from the previous cycle. It can be clearly seen that, in agreement with the findings of our previous study¹⁸, the cell under 180 MPa (Figure 2a) exhibits remarkable stability, retaining a discharge capacity of ~115 mA h g⁻¹ (approximately 50 % of the initial discharge capacity) after 15 cycles, with negligible change in overpotential (i.e., stable flat voltage plateaus). In contrast, the cell under non-pressure condition (see Figure S 4) shows rapid increase in overpotential with cycling, resulting in a drastic capacity fade to

below 50 mAh g⁻¹ (17 % of the initial value) within just 10 cycles. In Figure 2c), the cell under high stack pressure maintains a CE above 98 % over 150 cycles and exhibits an EE improvement of a factor of approximately 1.5 compared to the non-pressure cell. This pronounced performance enhancement can be attributed to the mitigation of interfacial degradation mechanisms in the pressurized system. In ASSFIBs, large volume change during the conversion reaction, in this case $\text{BiF}_3 + 3 \text{e}^- \rightarrow \text{Bi} + 3 \text{F}^-$ ($\Delta V = 29\text{--}40\%$, depending on the modification of BiF_3),^{37, 40, 41} can induce mechanical delamination at the solid-solid interfaces, leading to sudden or progressive loss of contact, increased impedance and inaccessibility of cathode active material. Our previous study¹⁸ reported that high stack pressure significantly helps to improve the cell's mechanical integrity, which mitigates contact loss between solid-solid particles and preserves electronic and ionic percolation pathway, thereby ensuring sustained access to electrochemically active BiF_3 particles throughout cycling. The comparison of the cross-section SEM images of $\text{BiF}_3|\text{BaSnF}_4|\text{Sn}$ cells after cycling with no pressure and 180 MPa are provided in Figure S 5. Furthermore, Figure 2b and d) demonstrate the C-rate capability of the cell under a stack pressure of 180 MPa. While the internal resistance (IR) drop increases with current density as expected, additional kinetic limitations appear to influence capacity retention. Notably, the observed capacity decay with increasing current density is mostly reversible upon returning to low currents. This effect is particularly more pronounced during charging and becomes more evident in the later stages of charge at high C-rates, indicating the presence of SOC-dependent processes, such as dynamic phase evolution, solid interphases from interfacial degradation at electrode-electrolyte interface.

Figure 2 The (dis)charge profiles of the cells cycled at $20 \mu\text{A cm}^{-2}$ under 180 MPa stack pressure in hot-press set up a) and c) corresponding Coulombic and Energy efficiency; b) Selected C-rate test of the cell under stack pressure of 180 MPa at 100 °C and the corresponding capacity retention d). The 0.01C is referred to as the measurements at 0.01C after cycling at 1C (302 mA g^{-1}).

3.2 Oxidefluoride formation under different stack pressures

View Article Online
DOI: 10.1039/D5TA06611E

Figure 3 a) Comparison of XRD patterns of the cells cycled at 100 °C with 40 $\mu\text{A cm}^{-2}$ under different stacking pressures for 1 cycle (charged to 1 V). Reflections marked by grey rectangles correspond to BiF_{0.1}O_{2.8} (1 0 1) and (2 -1 2); b) Phase analysis on the cells in a), with comparison of non-pressure cell; c) Phase analysis on the cells cycled at 100 °C with 40 $\mu\text{A cm}^{-2}$ (20 $\mu\text{A cm}^{-2}$ for the 150-cycled cell) for 2 cycles and long-term cycle. Corresponding partial fits are given in Figure S 7 and Figure S 10.

As previously reported³², BiF₃ cathodes undergo a complex phase evolution during discharge at 100 °C, transitioning sequentially from orthorhombic BiF₃ (o-BiF₃) to cubic BiF₃ (c-BiF_{3-x}) and then to a defect-rich orthorhombic phase (o'-BiF_{3-δ}), before forming metallic Bi. To further investigate the reversibility of this process, operando X-ray diffraction (XRD) was performed on the BiF₃|BaSnF₄|Sn cell upon charging, using identical temperature and current conditions. As shown in Figure S 6), operando XRD reveals partial reversibility of BiF₃ and the detrimental role of the oxidefluoride formation during discharge. Starting from the discharged state (cell

potential of 0.05 V), the metallic Bi ($R\bar{3}m$) fluorinated following the reverse pathway to discharging, initially forming o' -BiF_{3-δ} ($Fmmm$), followed by c -BiF_{3-x} ($Fm\bar{3}m$), with increasing F⁻ insertion into the lattice. This process is evidenced by the coherent increase in weight fraction of both phases observed. However, the oxidefluoride BiOF ($P4/nmm$) formed during discharging was found to be electrochemically inactive once formed and persists throughout the charging process. This is attributed to the thermodynamically stable nature of the Bi-O bond under cell operating conditions (100 °C), which makes F⁻/O²⁻ exchanging highly unfavorable. Also, oxygen diffusion is sluggish at solid-solid interfaces compared to fluoride ion diffusion, further limiting the reversibility³². Furthermore, when the cell is charged to 1 V, no orthorhombic BiF₃ ($Pnma$) was observed, and the cell volume of the formed c -BiF_{3-x} (~195.9(2) Å³) is smaller as compared to the initial value (~199.2(2) Å³) observed before the first discharge process³². This likely indicates a defect-rich structure and plausible oxygen incorporation in cubic phase during charge⁴².

To understand the effects of stack pressure on the phase evolution, *ex-situ* XRD was conducted on cells charged to 1 V after cycling under various stack pressures. Figure 3a) compares the *ex-situ* XRD patterns of those cells, and it can be seen, from the reflections marked by grey rectangles in Figure 3a), that the phase evolution of BiF_{0.1}O_{2.8} in the BiF₃ cathode exhibits pressure-dependent behavior. As a result obtained from detailed Rietveld analysis, the relative weight fraction of Bi-containing phases in BiF₃ cathode composite is shown in Figure 3b) (Partial fits are given in Figure S 7 and Figure S 10). In contrast to non-pressure conditions, even when only a moderate pressure of 20 MPa is applied, BiOF can no longer be detected; instead a F-rich oxidefluoride BiO_{0.1}F_{2.8} phase³⁵ ($P6_3/nmm$, $a=4.083$ Å, $c=7.323$ Å), is observed. This phase is structurally and chemically distinct to orthorhombic³⁷ and cubic BiF₃ modifications³² and BiOF³⁵ ($P4/nmm$, $a=3.746(9)$ Å, $c=6.226(1)$ Å), but has a very similar powder XRD pattern to trigonal BiF₃⁴³ ($P\bar{3}c$, $a=7.165$ Å, $c=7.318$ Å). However, there is a very strong difference in the unit cell volumes that have been observed for those phases. As an example, the overview of crystallographic data of BiF₃ and oxyfluorides obtained in the

partial fit of BiF_3 cathode composite of a cell pellet (dis-)charged (0.05-1 V) under a pressure of 180 MPa (Figure S 8) is list in Table S 1. The volume per $\text{BiO}_x\text{F}_{3-2x}$ ($0 \leq x \leq 1$) unit in trigonal BiF_3 and the compound observed by us is very different by $\sim 2.6\%$, whereas the orthorhombic modification observed fits with the volume within errors ($\sim -0.07\%$ volume difference to what has been reported in literature³⁷), and the smaller difference of the cubic modification is explained by its defect richer nature (as outlined in detail in our previous article³²). A volume difference of 2.6% for a symmetry distorted variant must thus have another origin. Given the volume evolution of $\text{BiO}_x\text{F}_{3-2x}$ on oxygen substitution (Table S 2 and Figure S 9) appears a fairly linear dependence on the oxygen content x in $\text{BiO}_x\text{F}_{3-2x}$ unit. The lattice parameters and volume we observed are very much in agreement with the reported hexagonal modification of $\text{BiO}_{0.1}\text{F}_{2.8}$, giving even a better fit with reduced R_{wp} value (in Table S1). Both, our previous study³² as well as this work have shown that in the pressure-free cells the presence of the tetragonal modification of BiOF (with a very low volume per $\text{BiO}_x\text{F}_{3-2x}$) is unquestionable. Since O substitution is thus a known phenomenon to occur within the cathode composite³², the identification of the low-O content bismuth oxyfluoride $\text{BiO}_{0.1}\text{F}_{2.8}$ with clearly different volume per $\text{BiO}_x\text{F}_{3-2x}$ unit than trigonal BiF_3 is well conclusive. However, one should be aware that the oxygen content cannot be determined precisely here, but that an overall fluorine-rich composition is indicated. Interestingly, the formation of $\text{BiO}_{0.1}\text{F}_{2.8}$ is contradictory to the mechanism for the formation of BiOF at the later discharge stage, which involves introduction of F^- defects into BiF_3 and accumulation of oxygen impurity during defluorination³². To clarify the origin of $\text{BiO}_{0.1}\text{F}_{2.8}$, cells cycled under 20 MPa and 180 MPa were analyzed by *ex-situ* XRD at discharged state (cell potential of 0.05 V). As shown in Figure S 11, no BiOF or $\text{BiO}_{0.1}\text{F}_{2.8}$ is detected at the discharged state, suggesting that $\text{BiO}_{0.1}\text{F}_{2.8}$ most likely forms under pressure in the later stage of charging (considering its fluorine-rich composition). This finding implies that stack pressure affects oxygen transport kinetics in BiF_3 composite, especially, O^{2-} diffusion appears to be suppressed within the investigated pressure range, which are critical for the phase evolution.

Notably, the pressure-dependent formation of $\text{BiO}_{0.1}\text{F}_{2.8}$ appears closely correlated to the ionic conductivity trend of BaSnF_4 discussed in Section 3.1. With increasing stack pressure from 20 MPa to 150 MPa (in Figure 3b), a reduced weight fraction of $\text{BiO}_{0.1}\text{F}_{2.8}$ is observed, with further increase in applied pressure, the amount of $\text{BiO}_{0.1}\text{F}_{2.8}$ rises again. This observation indicates the formation of $\text{BiO}_{0.1}\text{F}_{2.8}$ to be a consequence of the interplay between the kinetics of F^- and O^{2-} diffusion and their different activation volumes within BiF_3 cathode composite, which result in different pressure dependencies of the fluoride and oxide ion transport. Pure fluorides are in general poor oxygen conductors and, to our best knowledge, there is no study on oxygen conduction (and pressure dependency) within BaSnF_4 or other fluorides so far. However, many studies on the activation volume for O^{2-} in fluorite-type oxides and F^- in fluorite-type (-related) fluorides have been reported^{18, 44}. Christopoulos et al.⁴⁴ reported that the activation volume of O^{2-} diffusion in fluorite structured oxides (ThO_2 , UO_2 and PuO_2) at room temperature locate in the range of $10^{-14} \text{ cm}^3 \text{ mol}^{-1}$. Even for a superior oxide conductor ZrO_2 (doped with 8 mol% Y_2O_3)⁴⁵, the activation volume for O^{2-} transport at 750 °C is $2.08 \text{ cm}^3 \text{ mol}^{-1}$. In our previous study¹⁸, the determined activation volume of F^- in BaSnF_4 is $1.01(2) \text{ cm}^3 \text{ mol}^{-1}$ at 30 °C. Given that the activation volume of O^{2-} diffusion is significantly higher than F^- diffusion due to its larger ionic radius and higher covalency, our observation of reduced formation of bismuth oxyfluorides under pressure conditions are well in line with this behavior, suggesting that the O^{2-} diffusion process is considerably more sensitive towards stack pressure than F^- diffusion within the cathode composite. In addition, by studying low-pressure cells using operando XRD it is confirmed that the O species in the composite contribute to the formation of BiOF during discharging by plausible F^-/O^{2-} exchange mechanism at electrode-electrolyte interfaces³². Therefore, under stack pressure the eliminated voids and the improved contact between particles would certainly affect the O^{2-} diffusion at the interfaces. In summary, we interpret the pressure-dependent formation of $\text{BiO}_{0.1}\text{F}_{2.8}$ as follow:

From 20 MPa to 450 MPa, the solid-solid contact has been improved by increasing pressure and thus reduced the availability of the interfacial pathway for O^{2-} diffusion in the cathode composite, while the F^- transport is still dominated by the solid electrolyte. Initially, as the pressure increases from 20 MPa to 150 MPa, the suppression of O^{2-} diffusion combined with enhanced F^- transport leads to the reduced formation of $BiO_{0.1}F_{2.8}$. At pressures beyond 200 MPa, the ionic conductivity of $BaSnF_4$ significantly drops, limiting F^- transport to a level more comparable with O^{2-} diffusion. As a result, the weight fraction of the $BiO_{0.1}F_{2.8}$ phase increases again slightly, possibly indicating a pressure threshold beyond which F^- transport becomes a rate-limiting factor for oxyfluoride formation.

It is important to note that oxygen accumulation is a continuous process during cell operation, particularly in the system where the solid electrolyte is the main source of oxygen impurity³². Given that, prolonged cycling would unavoidably lead to an increase of oxidefluoride content. This agrees with the findings reported in Figure 3c), which compares the weight fraction of Bi-containing phases of cells under non-pressure conditions and constant pressure of 180 MPa after cycling. After 20 cycles without stack pressure, BiOF accounts for approximately two thirds of the Bi-containing phases. This finding is consistent with the severely decayed capacity to below 10 % of the theoretical value of 302 mAh g⁻¹. In contrast, under 180 MPa, the oxygen accumulation is significantly suppressed, with prolonged cycling its negative impact becomes pronounced. After 150 cycles, partial transformation of $BiO_{0.1}F_{2.8}$ to BiOF is observed, indicating gradual interfacial degradation. This observation is well reflected in the cell capacity decay observed in Figure 2a), confirming that by applying optimized pressure, the oxygen-accumulation-related degradation can be significantly reduced, but not eliminated. Thus, these results reveal a dual impact of stack pressure, promoting F^- diffusion and suppressing O^{2-} transport. Nevertheless, the presence of oxygen impurities remains a critical limitation, especially in long-term cycling, even at optimized pressure ranges. This emphasizes the importance of solid electrolyte purity, improved interfacial design and cell fabrication for ASSFIBs.

3.3 *In-situ* EIS-DRT analysis under different stacking pressures

As discussed in Section 3.1, the effect of stack pressure on BiF₃ cathode in ASSFIBs is closely related to the pressure-dependent ionic conductivity of BaSnF₄, as reflected by the shift of the flat voltage plateaus. However, cycling performance under pressure also reveals additional, nonnegligible contributions from kinetic limitations, particularly evident at later SOC's and correlating with the observed capacity decay. Such kinetic limitations are primarily attributed to charge transfer and ion diffusion processes within Bi-containing active materials, both of which are typically dynamic processes and SOC-dependent, each with distinct time constants which can be probed by EIS. To further understand these processes, *in-situ* EIS-DRT analysis was conducted at different OCVs during the first cycle under three pressure conditions as used for the cell characterization: moderate (20 MPa, Figure 4a), high (180 MPa, Figure 4b), and ultra-high (430 MPa, Figure 4c). The evolution of the Impedance spectra during discharge and charge during OCV monitoring is shown in Figure 4a-c next to the corresponding cell potential profiles, respectively. The corresponding DRT patterns are given in Figure 4d-f, indicated with specific time constant regimes. In particular, the SOC-dependent interfacial processes, which could be identified and categorized based on a comparison to literature values of typical kinetics processes in solid-state batteries^{26, 28} (one example of peak fitting and more comments on categorization are shown in Figure S 12, are plotted against the OCV in Figure 5a-b, and the detailed values are listed in Table S 3 to Table S 14.

As can be seen in Figure 5a-b and the corresponding DRT plots shown Figure 4d-f, the single peak with highest intensity in τ_3 (>1 s) regime is attributed to the ion F⁻ diffusion in the polycrystalline Bi-containing electrode materials (including bulk and grain boundary contributions). The less pronounced peaks located in the faster τ_2 (10⁻²-10⁰ s) regime correspond to the charge-transfer processes of both electrodes. These peaks also reflect the microstructural changes at electrode-electrolyte interfaces with a change of SOC's. In the τ_1 (10⁻⁵-10⁻² s) regime, we assign the smaller peak to the charge transfer across any interphases. In the τ_0 (<10⁻⁵ s) regime, contributions from solid electrolyte (i.e. contributions from both, bulk

and grain boundary responses of the nanocrystalline BaSnF_4 electrolyte, hereafter referred to as R_{SE}) and the potential contact resistance with the current collector are present. Due to the absence of a semicircle corresponding to BaSnF_4 within the measured frequency range, the R_{SE} was determined by the intercept of Nyquist plots on the real impedance axis and excluded from DRT fitting (Figure S 12). For all three pressure conditions, R_{SE} reveals a nearly constant value during both defluorination and fluorination, indicating SOC independence as would be expected for an electrolyte; the detailed values are listed in Table S 3 to Table S 14.

To confirm the dominance of BiF_3 cathode-related kinetic processes, a control EIS-DRT measurement was performed on a Sn/SnF_2 symmetric cell at half fluorination state (Sn to SnF_2 mass ratio is 1:1) and after 20 cycles (Figure S 13). It is found that such a Sn anode retains a relatively stable overpotential (slowly growing up to 15 mV over 24 cycles); its contribution to $\text{BiF}_3|\text{BaSnF}_4|\text{Sn}$ cell can thus be considered to be negligible. Furthermore, though the Sn/SnF_2 electrode exhibits similar time constants as BiF_3 cathode, compared to BiF_3 , the evolution of the peak's intensity is small and the corresponding resistances are much smaller (R_{ct} is around 20 times lower and R_{diff} is 50 times up to 2 magnitudes lower than that of the BiF_3 side). Hereby, it is confirmed that the measured kinetics in $\text{BiF}_3|\text{BaSnF}_4|\text{Sn}$ cells predominately reflect the behavior of BiF_3 cathode.

Figure 4 In-situ EIS-DRT analysis of the $\text{BiF}_3|\text{BaSnF}_4|\text{Sn}$ cells under stacking pressures. a) 22 MPa (left) Voltage profile with selected SOC's and (right) corresponding Nyquist plots during discharge and charge; b) 180 MPa (left) Voltage profile with selected SOC's and (right) corresponding Nyquist plots during discharge and charge; c) 430 MPa (left) Voltage profile with selected SOC's and (right) corresponding Nyquist plots during discharge and charge; d-f) Corresponding DRT patterns of the cells in a-c) with specific time constant regimes indicated (SE resistance is determined by the intercept of Nyquist plots at real impedance axis and is not included in DRT analysis due to the absence of a semicircle.)

Figure 5 Fitted resistances of the cells in Figure 4a-c) (interphase, charge transfer and diffusion through Bi-containing electrode active materials (CAMs)) are categorized according to their characteristic time constants.

As can be seen in Figure 5a-b, across three pressure conditions, the dominant SOC-dependent processes in the BiF_3 cathode composite are charge transfer (resistance referred to as R_{ct}) and ion diffusion processes (R_{diff}). Here F^- diffusion is considered to be the primary contribution due to the minor fraction of the oxygen impurity and much slower oxygen accumulation (predominantly along solid-solid interfaces)³². Similarly, it has been reported for oxide electrode materials such as $\text{Li}_7\text{Ti}_5\text{O}_{12}$ (LTO) in LIBs that those two processes are kinetically dominant and are sensitive to the SOC. As described in the previous chapter, the formation of oxidefluoride phases (e.g., BiOF and $\text{BiO}_{0.1}\text{F}_{2.8}$) is generally suppressed under the pressure conditions investigated in this work. Correspondingly, the associated R_{int} remains small during cycling and relatively stable during discharge. However, R_{int} exhibits a pronounced increase during charging, particularly for later SOC (discussion see later in this chapter). Thus, we conclude that the charge transfer and diffusion processes exhibit relatively high resistance values at the beginning of discharge, which can be attributed to the need for activation process and the low concentration of F^- defects in the fully charged BiF_3 lattice, requiring nucleation of the metallic Bi phase. Reversibly, the increase in R_{diff} and R_{ct} at the end of charging results

from the reduced availability of F^- defects and the poor electronic conductivity of BiF_3 and
oxidefluorides^{47, 48}, once present, compared to metallic Bi and CNF.

With increasing stack pressure, R_{diff} , R_{ct} and R_{int} all decrease significantly from moderate
(20 MPa) to high pressure (180 MPa), primarily due to drastically improved solid-solid
interparticle contact. However, at the highest pressure investigated (430 MPa), only a minor
impact of resistance reduction can be observed, though other effects, such as lattice distortion
and pressure-induced phase evolution, become dominant under this condition.

Notably, during the first defluorination, R_{diff} shows a complex behavior with two minima, in
agreement with three stages of structure evolution as described in our previous study³². With
 F^- extraction and Bi formation, orthorhombic BiF_3 transitions to cubic BiF_{3-x} , then an
orthorhombically distorted phase is formed prior to the formation of Bi metal becoming
predominant (referred to as Stage I, II and III marked in Figure 5a). It can be clearly seen that:
in Stage I R_{diff} decreases during the transition from o- BiF_3 to c- BiF_3 , then increase in stage II
with the o'- $BiF_{3-\delta}$ increases its fraction. Finally, in stage III, R_{diff} decreases when the phase
fraction of o'- $BiF_{3-\delta}$ decreases again. Considering that F^- diffusion within the grain of Bi-
containing active materials occurs mainly through a vacancy-exchange mechanism, an
increase in F^- vacancy concentration would initially enhance the ion mobility. Once the amount
of F^- defects reaches a certain threshold, the defects tend to cluster, leading to structural
distortion, and this appears to increase the resistance for F^- within the electrode. This change
is observed independent of stack pressure, indicating that this partial defluorination mechanism
is intrinsic to BiF_3 cathode. In the subsequent fluorination on charging, R_{diff} only possesses a
single minimum observed at OCVs between 0.35 to 0.45 V, coinciding with the formation of o'-
 $BiF_{3-\delta}$ at the beginning of fluorination. R_{diff} then increases again as fluorination proceeds via
formation of c- BiF_{3-x} to o'- $BiF_{3-\delta}$, consistent with the reversible phase transformation observed
by operando and ex-situ XRD. Noticeably, over stage II to III of defluorination, R_{diff} increases
at 430 MPa and even exceed the value under 180 MPa, being even 1.5 times higher than
before cycling. Given the defect-rich nature of intermediate o'- $BiF_{3-\delta}$ phase in this region, it

is plausible that this modification exhibits a distinct activation volume, making the F^- mobility more susceptible to pressure effect than in other modifications. This could be considered the most plausible origin for the capacity degradation described in Figure 1b. This is also in agreement with the increased R_{diff} under 430 MPa during charging in the OCV range from 0.35 to 0.5 V. Overall, these findings indicate that, despite enhanced interparticle contact at high stack pressures, which should facilitate charge transport, excessive pressure may instead negatively affect the ion F^- mobility within defect-rich phases of the Bi/BiF₃ cathode. We also note that the suppression of F^- mobility aligns well with the increased formation of BiO_{0.1}F_{2.8} under pressure beyond 200 MPa (see Section 3.2), likely arising from the competitive F^- and O²⁻ diffusion kinetics. This also explains the higher R_{int} observed at 430 MPa compared to 180 MPa (Figure 5b). Overall, the DRT study in combination with diffraction analysis shows that the stack pressure must be carefully optimized to balance between improved interfacial contact and adverse effects on ionic transport and phase stability.

4 Conclusions

In this work, we systematically investigated the effects of stack pressure on the electrochemical performance, phase evolution and kinetic behavior of BiF₃ cathode in all-solid-state fluoride-ion batteries (ASSFIBs), using BaSnF₄ as the solid electrolyte. By integrating galvanostatic cycling, operando & ex-situ XRD, and in-situ EIS-DRT analysis under varied stack pressures, we revealed a multifaceted pressure-dependent behavior that determines both thermodynamic aspects of phase formation and kinetic processes of ion transport within the cathode composite.

Our results demonstrated that applying high pressures (150-180 MPa) significantly improves cell capacity, coulombic efficiency, and long-term cycling stability. This enhancement is not only attributed to the improved mechanical contact between solid-solid interfaces and the increased ionic conductivity of BaSnF₄, which reduces the cell overpotential and collectively preserves electronic and ionic percolation pathways, but also to the suppression of the formation of oxygen-rich BiOF and corresponding interfacial degradation. In contrast, cells

under insufficient pressure suffer from interfacial degradation, including delamination and collective oxide/fluoride formation (BiOF or $\text{BiO}_{0.1}\text{F}_{2.8}$), explaining rapid capacity decay; the XRD result reveals that excessive pressures beyond 200 MPa lead to increased $\text{BiO}_{0.1}\text{F}_{2.8}$ formation, by suppressing F^- mobility and promoting competitive diffusion with oxygen impurities. While optimized stack pressure hinders the oxygen accumulation, the related interfacial degradation due to residual oxygen impurity remains unavoidable during prolonged cycling, emphasizing the critical need for electrolyte purification and interface design.

Through in-situ EIS-DRT analysis, we identified different kinetic processes and correlated to observed phase evolution and capacity decay. It is revealed that charge transfer and ion diffusion within Bi-containing active materials are the dominant SOC-dependent kinetic processes. The resistance contributions R_{diff} and R_{ct} exhibit strong correlation with structure evolution, evidenced by the observed changes of R_{diff} during defluorination and fluorination, respectively, highlighting the intrinsic nature of phase-change-driven F^- mobility in BiF_3 . Moreover, excessive stack pressure (430 MPa) was found to suppress F^- mobility, particularly at defect-rich stages.

Overall, our findings demonstrate that the influence of stack pressure on ASSFIBs is non-monotonic and governed by a complex interplay between mechanical contact, competing ion transport and phase evolution. Careful optimization of stack pressure is essential to balance mechanical stability, ionic transport and phase reversibility, and to ensure the high-performance fluoride-ion battery systems.

Data availability statements

The data supporting this article have been included as part of the Supplementary Information

Crystallographic data for [o-BiF₃ *Pnma*] has been deposited at the [ICSD] under [1269] and can be obtained from [<https://doi.org/10.1002/zaac.19774360112>].

Crystallographic data for [c-BiF₃ *Fm-3m*] has been deposited at the [ICSD] under [24522] and can be obtained from [<https://icsd.fiz-karlsruhe.de/display/details.xhtml>].

Crystallographic data for [Bi] has been deposited at the [ICSD] under [64703] and can be obtained from [<https://doi.org/10.1107/S0365110X62002297>].

Crystallographic data for [BiOF] has been deposited at the [ICSD] under [24096] and can be obtained from [U <https://icsd.fiz-karlsruhe.de/display/details.xhtml>].

Crystallographic data for [BiF₃ *P-3c*] has been deposited at the [ICSD] under [29325] and can be obtained from [<https://doi.org/10.1088/1742-6596/871/1/012007>].

Crystallographic data for [BiO_{0.1}F_{2.8} *P4/nmm*] has been deposited at the [ICSD] under [24056] and can be obtained from [<https://icsd.fiz-karlsruhe.de/display/details.xhtml>].

Crystallographic data for [BaSnF₄ *P4/nmm*] has been deposited at the ICSD] under [166207] and can be obtained from [<https://doi.org/10.1063/1.3234393>].
