## Amyloid $\beta$ -peptides 1–40 and 1–42 form oligomers with mixed $\beta$ -sheets†

Maurizio Baldassarre, <sup>a</sup> Cesare M. Baronio, <sup>a</sup> Ludmilla A. Morozova-Roche <sup>b</sup> and Andreas Barth <sup>\*a</sup>

Two main amyloid- $\beta$  peptides of different length ( $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$ ) are involved in Alzheimer's disease. Their relative abundance is decisive for the severity of the disease and mixed oligomers may contribute to the toxic species. However, little is known about the extent of mixing. To study whether  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  co-aggregate, we used Fourier transform infrared spectroscopy in combination with  $^{13}\text{C}$ -labeling and spectrum calculation and focused on the amide I vibration, which is sensitive to backbone structure. Mixtures of monomeric labeled  $\text{A}\beta_{40}$  and unlabeled  $\text{A}\beta_{42}$  (and *vice versa*) were co-incubated for  $\sim$ 20 min and their infrared spectrum recorded. The position of the main  $^{13}\text{C}$ -amide I' band shifted to higher wavenumbers with increasing admixture of  $^{12}\text{C}$ -peptide due to the presence of  $^{12}\text{C}$ -amides in the vicinity of  $^{13}\text{C}$ -amides. The results indicate that  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  form mixed oligomers with a largely random distribution of  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  strands in their  $\beta$ -sheets. The structures of the mixed oligomers are intermediate between those of the pure oligomers. There is no indication that one of the peptides forces the backbone structure of its oligomers on the other peptide when they are mixed as monomers. We also demonstrate that isotope-edited infrared spectroscopy can distinguish aggregation modulators that integrate into the backbone structure of their interaction partner from those that do not. As an example for the latter case, the pro-inflammatory calcium binding protein S100A9 is shown not to incorporate into the  $\beta$ -sheets of  $\text{A}\beta_{42}$ .

## Introduction

Alzheimer's disease – the most common form of dementia – is associated with the deposition of amyloid fibrils in the human brain. These consist mainly of  $\sim$ 40 residue-long proteolytic fragments of the  $\beta$ -amyloid precursor protein. The main variants of these amyloid- $\beta$  ( $\text{A}\beta$ ) peptides are 40 ( $\text{A}\beta_{40}$ ) and 42 ( $\text{A}\beta_{42}$ ) residues long. Although more of the shorter alloform  $\text{A}\beta_{40}$  is generated, the longer alloform  $\text{A}\beta_{42}$  dominates in the  $\text{A}\beta$  deposits in the human brain.<sup>1</sup> The  $\text{A}\beta_{42} : \text{A}\beta_{40}$  ratio is enhanced in some familial Alzheimer diseases, which likely causes the early onset of these diseases<sup>2–5</sup> due to increased toxicity from  $\text{A}\beta_{42}$ <sup>6</sup> and less protection by  $\text{A}\beta_{40}$ .<sup>5,7,8</sup> However, the situation is more complex than indicated by this simplistic explanation: a relatively small increase in the  $\text{A}\beta_{42} : \text{A}\beta_{40}$  ratio causes a dramatic increase in toxicity<sup>6</sup> and mixing two weakly toxic alloforms can generate high toxicity.<sup>9</sup> Thus, the properties of  $\text{A}\beta$  mixtures, including their toxicity, cannot simply be extrapolated from the properties of the pure peptides<sup>6,9,10</sup> and a recent review

concludes that studies of  $\text{A}\beta$  mixtures "will be crucial in understanding the toxic effects of  $\text{A}\beta$ ".<sup>11</sup> One of the most fundamental aspects in this context is whether or not different  $\text{A}\beta$  alloforms co-aggregate and form common structures. In a wider perspective, cross-reactivity of  $\text{A}\beta$  with other amyloidogenic proteins<sup>12–14</sup> may link neurodegenerative diseases that are so far considered to be different.

Co-incubation of  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  or cross-seeding leads to co-aggregation (cross-reactivity) in early aggregates,<sup>15,16</sup> modifies aggregation kinetics,<sup>6,7,10,17–24</sup> aggregate type distribution,<sup>6,10,22,23</sup> and may enable the formation of mixed fibrils,<sup>22,25,26</sup> although the latter has been disputed recently.<sup>16</sup> Most of the current evidence for co-aggregation in  $\text{A}\beta$  oligomers is indirect because either larger aggregates,<sup>10,16–19,22</sup> or monomeric peptides<sup>7,10</sup> have been observed. Direct evidence for mixing in  $\text{A}\beta$  oligomers has been obtained,<sup>15</sup> but using bulky labels attached to  $\text{A}\beta$ , which may affect aggregation properties. To the best of our knowledge there has not been a study that directly investigates the extent of mixture of  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  in  $\text{A}\beta$  oligomers with chemically unmodified peptides and that investigates the molecular architecture of mixed aggregates. This is in spite of the suggested importance of oligomers<sup>27,28</sup> and of the  $\text{A}\beta_{42} : \text{A}\beta_{40}$  ratio<sup>2,6</sup> for the severity of Alzheimer's disease.

To reveal whether and to what extent  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  form mixed aggregates, we used here isotope-edited infrared (IR)

spectroscopy. The main present use of this method is to determine the local conformation of polypeptides.<sup>29–31</sup> It has also been applied to separate the spectral contributions of different components in a complex<sup>32,33</sup> but only rarely to detect mixing of two polypeptides<sup>34,35</sup> or of two protein domains<sup>36</sup> in a common secondary structure. Our work uses the latter approach, provides a computational simulation of the effect, introduces the methodology to determine the randomness of mixing and discusses the sensitivity of the method for this property. We focus on the amide I vibration of the peptide backbone, which is sensitive to secondary structure and to further structural properties like the extension of  $\beta$ -sheets, their twist, the strength of hydrogen bonding, and the relative arrangement of adjacent strands.<sup>37–41</sup> Our results directly demonstrate co-aggregation of  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  in oligomeric aggregates. These aggregates are well structured and seem to contain a large proportion of antiparallel  $\beta$ -sheets. Advantageously, the results were obtained with chemically unmodified peptides, without addition of reporter compounds, and in aqueous solution.

## Results and discussion

### $\text{A}\beta$ hetero-oligomers with mixed isotope composition

Monomeric, recombinant peptides prepared at alkaline pH in  ${}^2\text{H}_2\text{O}$  were brought to  $\text{p}^2\text{H}$  7.4 and their IR spectra measured against a buffer spectrum after 20 min of incubation as described in ESI.† The preparation led to small-sized oligomers and additional larger aggregates for  $\text{A}\beta_{42}$  and  $\text{A}\beta_{42}$ -rich mixtures with  $\text{A}\beta_{40}$  when analyzed by gel electrophoresis after photo-induced crosslinking (see Fig. S5 of ESI†).

The IR absorbance and second derivative spectra of unlabeled and  ${}^{13}\text{C}, {}^{15}\text{N}$ -labeled  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  show the typical features of oligomers that are commonly assigned to antiparallel  $\beta$ -sheets (see Fig. S1 to S3 and discussion in ESI†). To test whether  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  become incorporated into the same oligomers, unlabeled  $\text{A}\beta_{42}$  was mixed with an equimolar concentration of uniformly  ${}^{13}\text{C}, {}^{15}\text{N}$ -labeled  $\text{A}\beta_{40}$  at alkaline  $\text{p}^2\text{H}$  and incubated at  $\text{p}^2\text{H}$  7.4. In a further experiment, labeled and unlabeled peptides were exchanged. The second derivative spectra of the 1 : 1 mixtures are shown in Fig. 1A and B (solid lines). Negative bands in these spectra correspond to component bands in the absorbance spectra. Also shown in Fig. 1A and B are calculated spectra (dashed lines) obtained by averaging the individual oligomer spectra shown in Fig. S1 and S2† (for the corresponding absorbance spectra see Fig. S3†). The calculated spectra are expected when unlabeled and labeled peptides do not mix, but rather give rise to distinct all-unlabeled and all-labeled oligomers. The positions of the main bands in these spectra are the same as in the individual oligomer spectra. In contrast, the real mixture spectra exhibit shifts of all main bands and a loss in intensity of the  ${}^{12}\text{C}$ -band (near  $1625\text{ cm}^{-1}$ ). This clearly indicates that the backbones of  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  interact in the oligomers and that this interaction influences the vibrational coupling that determines the band position of the  $\beta$ -sheet band.

Fig. 1 Spectra of the second derivative of IR absorbance of oligomers obtained from mixtures of unlabeled  $\text{A}\beta_{42}$  and labeled  $\text{A}\beta_{40}$  (A and C) and unlabeled  $\text{A}\beta_{40}$  and labeled  $\text{A}\beta_{42}$  (B and D). Real spectra of 1 : 1 mixtures are shown in panels (A) and (B) (solid lines), together with averaged spectra of the pure compounds (dashed lines). In panels (C) and (D), the spectra of several ratios of unlabeled and labeled peptides (9 : 1, 3 : 1, 1 : 1, 1 : 3, 1 : 9) are shown together with those of the pure oligomers obtained from unlabeled (blue) and labeled (red) peptides. The arrows in panels (C) and (D) indicate the changes in intensity and band position of the main  ${}^{13}\text{C}$ -band upon  ${}^{13}\text{C}$ -enrichment.

## Band shifts upon isotopic dilution

To discuss further the structural basis of the  $\text{A}\beta_{42}:\text{A}\beta_{40}$  mixing effect, panels C and D of Fig. 1 show spectra recorded for a number of different  $\text{A}\beta_{42}:\text{A}\beta_{40}$  ratios, where one of the peptides was labeled. They reveal gradual upshifts of the main  $^{12}\text{C}$ - and  $^{13}\text{C}$ - $\beta$ -sheet bands (near  $1625$  and  $1580\text{ cm}^{-1}$ , respectively) and a downshift of the minor  $\beta$ -sheet band (near  $1680\text{ cm}^{-1}$ ) upon isotopic dilution. Such band shifts upon isotopic dilution have been observed previously.<sup>34,36,42-46</sup>

We chose the  $^{13}\text{C}$ -band for further evaluation, because it can be detected even at low  $^{13}\text{C} : ^{12}\text{C}$ -ratio in second derivative spectra. The position of this band is plotted in Fig. 2 and reflects the continuous downshift of the band upon  $^{13}\text{C}$ -enrichment. The different end points of the curves (when only labeled peptide is present) reflect the different structures of the pure oligomers (see Fig. S2†).

We explain the observed  $^{13}\text{C}$ -band shift by the formation of  $\beta$ -sheets with mixed isotopic composition, *i.e.* sheets that

consist of  $^{12}\text{C}$ - and  $^{13}\text{C}$ -strands. For the experiments shown in Fig. 1C and D, this means that the sheets contain strands from  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$ . This interpretation will be tested in the following sections by calculations and control experiments.

## Calculated amide I spectra of antiparallel $\beta$ -sheets with mixed isotope composition

To support our explanation for the shift of the  $^{13}\text{C}$ -band upon isotopic dilution we discuss now spectrum calculations that simulate the above experiments. The aim was to reproduce the effects of isotopic dilution in a qualitative way.

Details of the calculations are provided in ESI.† In brief, amide I spectra were calculated using coupling constants from density functional theory for nearest neighbor interactions and from transition dipole coupling for other interactions. Diagonal and non-diagonal elements of the mass-normalized force constant matrix considered the carbon isotope of the respective amide group(s). Spectra were calculated from 3000 sheets with a statistical distribution of  $^{12}\text{C}$ - and  $^{13}\text{C}$ -strands at a given  $^{13}\text{C} : ^{12}\text{C}$  ratio. Errors in calculated band positions were obtained by repeating the calculations 20-times.

Antiparallel  $\beta$ -sheets of different sizes generated qualitatively similar spectra. As an example, Fig. 3 shows results obtained with a sheet of 6 strands and 10 residues (9 complete amide groups) per strand. The main  $^{12}\text{C}$ -band near  $1622\text{ cm}^{-1}$  loses intensity already at low  $^{13}\text{C} : ^{12}\text{C}$ -ratios whereas the  $^{13}\text{C}$ -band is observed for all ratios. It shifts gradually down with increasing  $^{13}\text{C} : ^{12}\text{C}$ -ratios as observed in the experiments. These simulations show that the experimental result can be explained by mixing strands with different carbon isotopes in the same  $\beta$ -sheet. This conclusion is independent from the molecular

**Fig. 2**  $^{13}\text{C}$ -band position as a function of the molar fraction of labeled peptide. The black squares and lines are for  $\text{A}\beta_{42}:\text{A}\beta_{40}$  mixtures, where one of them was labeled. The gray stars and lines are for mixtures of labeled and unlabeled versions of the same peptide. (A)  $^{13}\text{C}$ - $\text{A}\beta_{42} : ^{12}\text{C}$ - $\text{A}\beta_{40}$  (black) and  $^{12}\text{C}$ - $\text{A}\beta_{42} : ^{13}\text{C}$ - $\text{A}\beta_{42}$  (gray) mixtures. (B)  $^{12}\text{C}$ - $\text{A}\beta_{42} : ^{13}\text{C}$ - $\text{A}\beta_{40}$  (black) and  $^{12}\text{C}$ - $\text{A}\beta_{40} : ^{13}\text{C}$ - $\text{A}\beta_{40}$  (gray) mixtures. The large symbols indicate band positions that were directly determined from the second derivative spectra except for the data points at 0.1 molar fraction of labeled peptide, which were obtained from a fit as described in ESI.† The small symbols show the original band positions in the second derivative spectra for these data points. Note that the data for completely labeled peptides in each panel are from two independent series of experiments. The agreement between the band positions demonstrates the excellent reproducibility of the spectra.

**Fig. 3** Calculated amide I spectra for an antiparallel  $\beta$ -sheet with 6 strands and 10 residues per strand (9 complete amide groups). The blue and red spectra were calculated for entirely unlabeled and labeled sheets, respectively. The gray spectra were calculated for different molar fractions of  $^{13}\text{C}$ -peptides, as used in the experiments (0.1, 0.25, 0.5, 0.75, 0.9). Each simulated spectrum is the average of the spectra from 60 000 sheets with a statistical distribution of labeled and unlabeled strands at a given  $^{13}\text{C} : ^{12}\text{C}$ -ratio.  $^{13}\text{C}$ -enrichment gradually shifts the  $^{13}\text{C}$ -band from  $1603.5$  to  $1586.2\text{ cm}^{-1}$ . The  $^{12}\text{C}$  band position for the completely unlabeled sheet is  $1622.2\text{ cm}^{-1}$ .

architecture of the  $\beta$ -sheets as qualitatively similar results were obtained for parallel sheets (see Fig. S7†).

While the band positions of the completely labeled and unlabeled 6-stranded sheet are in reasonable agreement with the experimental values, the  $^{13}\text{C}$ -band shift between 10% and 100%  $^{13}\text{C}$  content is calculated to be larger than experimentally observed ( $17\text{ cm}^{-1}$  versus  $9\text{--}12\text{ cm}^{-1}$  observed in the four mixing experiments shown in Fig. 2). The calculated shift is smaller for a parallel  $\beta$ -sheet of the same size ( $14\text{ cm}^{-1}$ ) but these calculations fail to reproduce the high wavenumber band that is clearly observed in the experimental spectra (compare Fig. 1 and S7†). The discrepancy is not due to our use of ideal  $\beta$ -sheet structures for the calculations, as similar or larger shifts were obtained for a 6-stranded antiparallel sheet from a streptavidin mutant ( $20\text{ cm}^{-1}$ ) and in a calculation for an ideal antiparallel sheet in which the vibrational coupling constants were varied statistically to simulate structural disorder ( $17\text{ cm}^{-1}$ ).

The likely reason for the discrepancy between the experimental and the calculated  $^{13}\text{C}$ -band shift is the internal structure of the oligomers as the shift is sensitive to the number of adjacent strands that contain the same carbon isotope.<sup>36,46</sup> When this number is one, the calculated  $^{13}\text{C}$ -band shift (between 10% and 100%  $^{13}\text{C}$  content) was  $24\text{ cm}^{-1}$  for large parallel sheets.<sup>36,46</sup> When this number is two, the shift decreased to  $18\text{ cm}^{-1}$ . The shift decreased further when the number of adjacent strands with the same carbon isotope was increased to three or four. We confirmed this trend in our own calculations with 6-stranded sheets that were composed of building blocks of two adjacent  $\beta$ -strands with the same carbon isotope. The shift was now reduced to  $10\text{ cm}^{-1}$ , which compares favorably to the  $9\text{--}12\text{ cm}^{-1}$  shift in the four mixing experiments shown in Fig. 2. Therefore a plausible explanation of our results is that each peptide contributes two or more adjacent strands to the oligomers. Our shifts are smaller than those calculated by Moran *et al.* because we use sheets with a much smaller number of strands.

#### Explanation of the band shifts upon isotopic dilution

The reason for the spectral shifts can be found in the decreased coupling between neighboring oscillators in a  $\beta$ -sheet with mixed isotope composition compared to an all-unlabeled or all-labeled sheet. This is shown schematically in Fig. 4 using an ideal anti-parallel  $\beta$ -sheet to illustrate the principle. In a  $\beta$ -sheet composed entirely of either unlabeled or labeled strands, such as the one shown in the top panel, the local amide I' oscillations of individual peptide groups (dashed ellipses) couple strongly because (1) they have a similar vibrational frequency, (2) the main component of their transition dipole moments is oriented in the same direction and (3) they are close in space. This delocalizes the vibrations over up to 12 strands<sup>47</sup> (solid ellipse). The strongest coupling of a particular amide group in an anti-parallel  $\beta$ -sheet is with the two hydrogen bonded amide groups in the adjacent strands and with the diagonally opposed amide group in one of the adjacent strands.<sup>37,48</sup> Intrastrand coupling between nearest neighbors is smaller but still significant. Nevertheless and to simplify the illustration, only the strongest

Fig. 4 Simplified explanation for the spectral effects of mixing labeled and unlabeled strands in a  $\beta$ -sheet. In the sheet, carbon, nitrogen and oxygen atoms are shown in gray, blue and red, respectively. The dashed ellipses denote individual amide I oscillators, they are blue for  $^{12}\text{C}$ -amides and red for  $^{13}\text{C}$ -amides. The solid ellipse denotes a delocalized vibration due to coupling of the indicated individual oscillators. The dashed and solid spectra on the side show the main  $\beta$ -sheet absorption band before and after coupling is established (top), as well as before and after it is partially broken (bottom) for the main  $^{12}\text{C}$ - (blue) and the main  $^{13}\text{C}$ -band (red).

interaction is considered in Fig. 4. Coupling affects band positions and leads to a downshift in case of the main  $\beta$ -sheet band. This is shown in the set of spectra on the right side of the top panel of Fig. 4. Stronger coupling leads to a larger downshift, which increases with sheet flatness and number of incorporated strands (usually up to 10 strands)<sup>37–40</sup> and is, among others, the reason for the downshifted absorption of  $\beta$ -sheets in amorphous aggregates compared to those in soluble proteins. The above discussion indicates that IR spectroscopy is sensitive to structural variations in  $\beta$ -sheets that occur within a length scale of 10–12 strands.

In the case of an isotopically mixed  $\beta$ -sheet (bottom panel of Fig. 4), where fully unlabeled and fully labeled strands alternate randomly, the difference in the intrinsic vibrational frequencies of the amide oscillators makes that unlabeled (blue ellipses) and labeled (red ellipses) oscillators couple only weakly. Therefore, the vibration is less delocalized over the span of the sheet and more localized on the individual strands. The net effect is that the vibrational frequencies of both unlabeled and labeled oscillators are closer to those of the uncoupled, hydrogen-bonded amide carbonyls ( $\sim 1645\text{ cm}^{-1}$  for  $^{12}\text{C}=\text{O}$ , and  $\sim 1600\text{ cm}^{-1}$  for  $^{13}\text{C}=\text{O}$ ), and the corresponding  $\beta$ -sheet absorption bands shift to higher wavenumbers compared to a fully unlabeled or fully labeled sheet.

The opposite phenomenon occurs for the high wavenumber band of anti-parallel  $\beta$ -sheets, which experiences a downshift

upon loss of coupling. The smaller magnitude of the shift, together with the moderate intensity of this band, makes it less useful in the study of amyloid- $\beta$  oligomers compared to the main  $\beta$ -sheet band.

#### Control: A $\beta$ homo-oligomers with mixed isotope composition

If the  $^{13}\text{C}$ -band shift indicates isotopically mixed  $\beta$ -sheets, then similar shifts must be observed when labeled and unlabeled versions of the same peptide are mixed in homo-oligomers. In such experiments, labeled and unlabeled peptides form randomly mixed  $\beta$ -sheets because they are chemically identical. Our experiments with homo-oligomers of varying isotope composition resulted in similar  $^{13}\text{C}$ -band shifts, which are included as gray lines in Fig. 2. The results with homo-oligomers support our interpretation that A $\beta_{42}$ :A $\beta_{40}$  hetero-oligomers form mixed  $\beta$ -sheets.

#### Evidence for random mixing in hetero-oligomers

The  $^{13}\text{C}$ -band shifts of the homo-oligomers shown in Fig. 2 serve as reference curves for random mixing. They superimpose well with the curves for A $\beta_{42}$ :A $\beta_{40}$  mixtures indicating that these two peptides form common  $\beta$ -sheets which contain a random or close to random mixture of A $\beta_{40}$  and A $\beta_{42}$  strands.

In our experiments, A $\beta_{42}$ :A $\beta_{40}$  oligomers of different sizes are formed (see ESI $\dagger$ ), which might have different mixing preferences. The limiting cases are randomly mixed A $\beta_{42}$ :A $\beta_{40}$  oligomers on the one hand and chemically homogeneous aggregates, *i.e.* pure A $\beta_{42}$  or pure A $\beta_{40}$  oligomers, on the other hand. Intermediate cases are also conceivable. When one of the two A $\beta$  alloforms is labeled, such different kinds of oligomers will have different  $^{13}\text{C}$ -band positions for a given isotope ratio according to the calculations shown in Fig. S8. $\dagger$  The  $^{13}\text{C}$ -band position will be lower for the aggregates with higher purity than for aggregates with a statistical A $\beta_{42}$ :A $\beta_{40}$  composition. Experimentally, these different band positions will be difficult to distinguish because the bands are likely to overlap. The overlap will lead to a single broad  $^{13}\text{C}$ -band that is downshifted with respect to that for randomly mixed aggregates at all isotope ratios. This is not observed. Instead,  $^{13}\text{C}$ -band positions for the heterogeneous A $\beta_{42}$ :A $\beta_{40}$  mixtures (black curves in Fig. 2) superimpose well on those for homogeneous oligomers, which have a statistical distribution of labeled and unlabeled strands (gray curves in Fig. 2). Therefore none of the dominant oligomers in our A $\beta_{42}$ :A $\beta_{40}$  samples deviates enough from the random mixing case to produce a detectable effect.

#### Control: A $\beta$ hetero-oligomers from unlabeled peptides

While the isotope effect evident in Fig. 1 and 2 reveals mixing of A $\beta_{40}$  and A $\beta_{42}$ , it masks band shifts due to structural differences between the homo-oligomers and the hetero-oligomers. Therefore we repeated the experiment with unlabeled peptides. When unlabeled A $\beta_{40}$  and A $\beta_{42}$  were mixed, both the band position of the main  $\beta$ -sheet and that of the broad band near 1645  $\text{cm}^{-1}$  shifted in a nearly linear fashion between the extreme values of the pure compounds. This is shown in panels A and B of Fig. 5. Please note that this series of experiments is completely independent from the

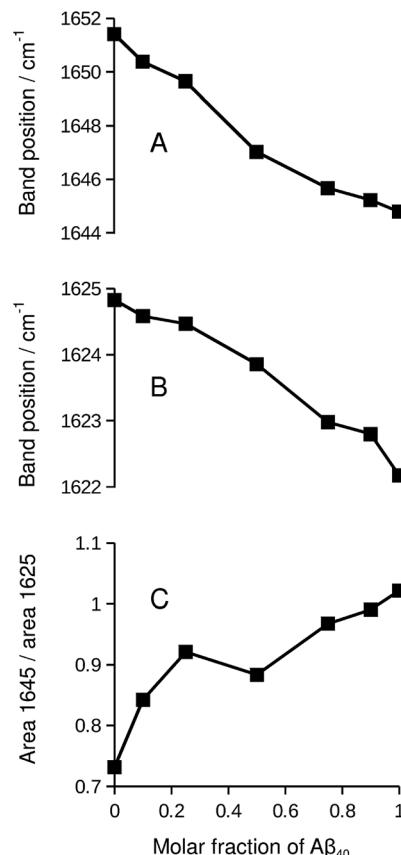

Fig. 5 Spectral changes upon increasing the A $\beta_{40}$  content in A $\beta_{42}$ :A $\beta_{40}$  mixtures of unlabeled peptides. (A) Band position of the broad band near 1650  $\text{cm}^{-1}$  in the second derivative spectra. Only for this panel, the smoothing range for calculating the second derivative was increased from our standard value of 13 points to 25 points to obtain a more accurate description of the small band of the A $\beta_{42}$  sample. (B) Band position of the  $\beta$ -sheet band near 1625  $\text{cm}^{-1}$  in the second derivative spectra. (C) Integrated absorbance near 1645  $\text{cm}^{-1}$  divided by the integrated absorbance near 1625  $\text{cm}^{-1}$ . Integration in the ranges 1650–1640  $\text{cm}^{-1}$  and 1630–1620  $\text{cm}^{-1}$  was done with method E of the Bruker OPUS software with respect to a baseline drawn between the averaged absorbance in the 1700–1695  $\text{cm}^{-1}$  and in the 1610–1605  $\text{cm}^{-1}$  range.

ones shown in Fig. 1. Therefore the band positions of the pure compounds are slightly different. The band position of the A $\beta_{42}$  spectrum in Fig. 5 (1624.8  $\text{cm}^{-1}$ ) is the lowest measured for six independent samples (average  $1625.5 \pm 0.4 \text{ cm}^{-1}$ ). The band position for A $\beta_{40}$  (1622.2  $\text{cm}^{-1}$ ) in Fig. 5 is very close to the average of  $1622.3 \pm 0.1 \text{ cm}^{-1}$  determined for three samples.

Concomitant with the shifting band positions, the broad band near 1645  $\text{cm}^{-1}$  intensifies as the A $\beta_{40}$  content increases (see also Fig. S1 $\dagger$ ). This may indicate that there is more random coil structure in the A $\beta_{40}$  oligomers. However, intensities in second derivative should be compared with care as they also depend on the band width. Therefore we sought confirmation for the above interpretation in the respective absorbance spectra and found it confirmed: the absorbance spectrum of A $\beta_{40}$ , but not that of A $\beta_{42}$ , shows a pronounced shoulder near 1640  $\text{cm}^{-1}$  that can be assigned to random coil structures as

shown in Fig. S3.† In the mixtures, the absorbance in the  $1650\text{--}1640\text{ cm}^{-1}$  region increases relative to that in the  $1630\text{--}1620\text{ cm}^{-1}$  region as the  $\text{A}\beta_{40}$  content increases (panel C of Fig. 5).

As the curves in Fig. 5 are nearly linear, they indicate a gradual transition between the spectra of the pure oligomers and thus a gradual shift between the backbone structures of  $\text{A}\beta_{42}$  oligomers and of  $\text{A}\beta_{40}$  oligomers as the peptide composition of the oligomers changes. This result has several implications:

(i) As a control experiment it indicates that the backbone structures of the mixed aggregates are similar to those of the pure oligomers. The shift of the main  $\beta$ -sheet band (panel B) is much smaller than the  $^{13}\text{C}$ -band shift in Fig. 5. Therefore, a conformational effect can be excluded as an explanation for the  $^{13}\text{C}$ -band shift. Note also that the shifts in Fig. 5 depend on the  $\text{A}\beta_{42} : \text{A}\beta_{40}$  ratio, whereas those in Fig. 1 and 2 depend on the  $^{13}\text{C} : ^{12}\text{C}$ -ratio. In the latter experiments, increasing the  $\text{A}\beta_{40}$  content leads to a downshift of the  $^{13}\text{C}$ -band when  $\text{A}\beta_{40}$  is labeled, but to an upshift when it is not labeled.

(ii) From a methodological perspective, Fig. 5 demonstrates that mixing can only be detected with the help of isotope labels (Fig. 1) because the curves in Fig. 5 are close to those expected for the case when  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  do not mix.

(iii) Regarding the biological system, Fig. 5 shows that none of the peptides forces the backbone structures of its pure oligomers on the mixed aggregates when the two peptides co-aggregate from a mixture of monomers. Otherwise, the curves in Fig. 5 should be more curved.

### Control: $\text{A}\beta_{42}$ and S100A9

The ability of  $\text{A}\beta_{42}$  and  $\text{A}\beta_{40}$  to form mixed oligomers has the natural consequence that they mutually influence their aggregation properties. In contrast, other interaction partners may affect aggregation without integrating into the backbone structure of the  $\text{A}\beta$  aggregates. In the following we will show that isotope-edited IR spectroscopy can distinguish between these two cases and thus provides information that is complementary to that obtained from other aggregation assays.

As an example for the second case, we chose the brain-expressed, pro-inflammatory calcium binding protein S100A9, which is also called migration inhibitory factor-related protein 14 (MRP14) or calgranulin B. It forms amyloids on its own and is known to interact with  $\text{A}\beta$ , which enhances the amyloidogenicity of both.<sup>49,50</sup> In this case the interaction proceeds *via* transient hydrophobic contacts involving side chains,<sup>49,50</sup> rather than *via* direct interaction between backbone segments of the two proteins.

The IR absorption spectrum of S100A9 in the amide I' region is shown in black in panels A and C of Fig. 6. It exhibits three main components. A strong, sharp band at  $1650\text{ cm}^{-1}$  originates from  $\alpha$ -helices, the dominant secondary structure in the protein. The minor band at  $1631\text{ cm}^{-1}$ , usually assigned to  $\beta$ -sheet structures, rather originates from solvent-exposed and highly hydrated stretches of  $\alpha$ -helices as there are no  $\beta$ -sheets in this protein.<sup>51</sup> The band at  $1675\text{ cm}^{-1}$  originates from turns.

Fig. 6 Oligomer formation by unlabeled and labeled  $\text{A}\beta_{42}$  in the presence of S100A9. Panels (A), (B) and (C), (D) refer to experiments performed using unlabeled and labeled  $\text{A}\beta_{42}$ , respectively. S100A9 is unlabeled in both experiments. Panels (A) and (C) show spectra of the pure components and panels (B) and (D) spectra of the 1 : 1 mixtures (w/w). "Experiment" refers to the experimental spectrum and "Average" to the average spectrum of the pure components, which is the expected mixture spectrum in the absence of structural changes.

The spectrum of the mixture with unlabeled  $\text{A}\beta_{42}$  oligomers is shown as blue spectrum in panel B together with a calculated spectrum of the 1 : 1 mixture (average spectrum of the pure components, dashed spectrum). The two spectra are virtually superimposable, with all the main features of the  $\text{A}\beta_{42}$  oligomer spectrum being preserved. A small ( $\sim 1\text{ cm}^{-1}$ ) downshift of the main  $\beta$ -sheet band can be observed (arrowhead 1) and is likely due to accelerated aggregation in the presence of S100A9. This interpretation is based on the observation that the position of this band downshifts with increased aggregation time.<sup>52</sup>

The same experiment was performed with labeled  $\text{A}\beta_{42}$  oligomers, as shown in panels C and D. Again, the calculated (dashed) and experimental (solid red) spectra of the 1 : 1 mixture are virtually superimposable and a small downshift of

the main  $\beta$ -sheet band of labeled  $\text{A}\beta_{42}$  oligomers can be observed (arrowhead 2). In contrast to the  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  mixtures, no upshift of the main  $^{13}\text{C}$ - $\beta$ -sheet band occurs when S100A9 is added to  $\text{A}\beta_{42}$ . This indicates that the upshift observed for  $\text{A}\beta_{40}:\text{A}\beta_{42}$  mixtures is not induced by transient, hydrophobic interactions between side chains as they occur between S100A9 and  $\text{A}\beta$ .

## Conclusions

Our experiments and control experiments clearly demonstrate that  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  form mixed oligomers, when they are mixed as monomers before aggregation is initiated. Mixing occurs on the level of secondary structure, where the  $\text{A}\beta_{40}$  backbone is in direct interaction with the  $\text{A}\beta_{42}$  backbone in the  $\beta$ -sheets of the oligomers. Mixing of  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  strands in the  $\beta$ -sheets is random or close to random. This structural information was inferred from band shifts in the IR spectrum, when one of the peptides was  $^{13}\text{C}$ -labeled. The different carbon isotopes in the mixed sheets disrupt the interstrand vibrational coupling, which leads to an upshift of the main  $\beta$ -sheet band. This conclusion is also supported by our spectrum calculations, which reproduce the shifts observed in the experiments. The best agreement between calculations and experiments is obtained when we assume that each peptide contributes two adjacent strands to the oligomers.

The backbone structures of mixed  $\text{A}\beta_{42}:\text{A}\beta_{40}$  oligomers are intermediate between those of the pure aggregates. There is no indication that one of the alloforms forces its preferred structure on the other alloform when they are mixed as monomers. This conclusion is based on band shifts observed for mixtures of unlabeled peptides, which depend linearly on the composition of the aggregates.

The random or close to random mixing of  $\text{A}\beta_{40}$  and  $\text{A}\beta_{42}$  in the  $\beta$ -sheets of oligomers occurs in spite of their different propensities to aggregate<sup>6,10,16,21,23</sup> and the different oligomer structures that they adopt<sup>23</sup> (see also Fig. S1†). Our findings are in line with previous more qualitative conclusions using chemically modified peptides<sup>15</sup> or peptides attached to a support<sup>10</sup> and with conclusions drawn indirectly from the observation of fibril formation.<sup>16</sup> Our work adds information on the extent of mixing and on the structural architecture of mixed oligomers. It strengthens the view that heterogeneous oligomers are relevant for Alzheimer's disease. In addition, it highlights the necessity to consider them in the amyloid field in general, since similar mixed oligomers may assemble under many other amyloidogenic conditions in several diseases.

## Conflicts of interest

There are no conflicts to declare.

## Acknowledgements

We are grateful to Chao Wang for purification of S100A9 and to Eeva-Liisa Karjalainen for the original version of the Matlab program for spectrum calculations. We acknowledge support
