A luminescent metal–organic framework as an ideal chemosensor for nitroaromatic compounds†

Hongming He,^a Si-Hang Chen,^a De-Yu Zhang,^a En-Cui Yang ^{*a} and Xiao-Jun Zhao ^{*ab}

A luminescent two-dimensional metal–organic framework, [(Pr₂(TATMA)₂·4DMF·4H₂O)_n] (1), was solvothermally synthesized based on the semi-rigid organic ligand 4,4',4''-s-triazine-1,3,5-triyltri-*m*-aminobenzoate (H₃TATMA). 1 possesses binuclear {Pr₂(COO)₆} subunits and fully deprotonated TATMA³⁻ organic ligands, which can be further simplified into a 3,6-connected *kfd* topology with the Schläfli symbol of (4³)₂(4⁶·6⁶·8³). More importantly, 1 displays fast and reversible solid-state detection of nitroaromatic compounds, especially for TNP, *via* a luminescence response.

Introduction

Nitroaromatic compounds (NACs) are common toxic and hazardous chemicals, which should not be neglected in our daily life. To date, NACs have been extensively used in many fields including industry, agriculture, and military. Due to its extensive use and difficulty in degradation, it triggers a series of security and environmental issues.¹ Hence, it is vitally important to effectively detect NACs for homeland security and environmental protection. It is noteworthy that 2,4,6-trinitrophenol (TNP) is the most common nitro explosive, which possesses stronger explosive force as compared to other nitro explosives. In addition, TNP is also widely applied in the fireworks, industrial dye, and leather fields. Due to its frequent and excessive use, a large number of PAs are released into the environment; this leads to a series of serious health complications including genovariation, respiratory infection, and anemia. Thus, it is particularly important to efficiently detect TNP among all the NACs.

Metal–organic frameworks (MOFs)^{2–5} can be considered as a new class of fascinating porous crystalline materials, which have attracted significant attention in the past few decades. Due to their intriguing varieties of architectures, high surface areas, and tunable structures, MOFs have emerged as promising materials with a wide range of potential applications. Among

them, luminescent MOFs,^{6–14} as fast-growing organic–inorganic hybrid luminescent crystalline materials, have received significant attention for the detection of hazardous substances because luminescent MOFs have the unique advantage of functional diversity. Luminescent MOFs are composed of two different parts: metal ions/clusters and organic bridging ligands, which can be considered as light-emitting sources. Numerous factors, including metal ion, organic ligand, temperature, and solvent system, can affect the structural assembly process and luminescent properties of these luminescent MOFs.^{15–18} Among them, the organic ligand plays the most important role in adjusting their structure and functionality. Recently, extensive efforts have been focused on the design of novel semi-rigid tritopic ligands such as 1,3,5-tri(4-carboxyphenoxy)benzene^{19–21} and 1,3,5-tri(4-(2*H*-tetrazol-5-yl)phenoxy)benzene.²² These ligands can be widely applied to construct MOFs due to their intriguing architectures and remarkable properties. On the other hand, the functional luminescent ligands not only can be used to construct luminescent MOFs, but also contain functional groups to enhance the recognition effect of ions, solvents, and small molecules. Hence, triazines as functional groups can be designed and synthesized to form luminescent MOFs as sensors because they generate interactions between guest molecules and the MOF skeleton to affect their luminescent properties. Motivated by the abovementioned aspects, our research strategy has evolved as follows. Considering that triazines can serve as a hydrogen-bonding recognition group, we introduced it into semi-rigid tritopic ligands, which can serve as a luminescent emitting source for the detection of toxic and harmful substances. Recently, some luminescent MOFs based on semi-rigid tritopic ligands have been prepared as sensors. For example, Zhang *et al.* reported a two-dimensional (2D) Eu-MOF, [Eu(L)(H₂O)₂]·NMP·H₂O (H₃L = 4,4',4''-s-triazine-1,3,5-triyltri-*m*-aminobenzoate).²³ The resultant sample can detect Fe²⁺/Fe³⁺ cations and exhibit high sensitivity for Cr₂O₇²⁻ anions. Qian *et al.* have reported a Ln-MOF, Tb(TATAB)·(DMF)₄·(H₂O)·(MeOH)_{0.5}

Scheme 1 The semi-rigid organic ligand H_3TATMA .

($H_3TATAB = 4,4',4''$ -s-triazine-1,3,5-triyltri-*p*-aminobenzoic acid), which exhibits high selectivity for Hg^{2+} ions.²⁴ However, no previous investigations have reported the use of these MOFs as sensors for NACs besides a zeolitic MOF, $(Me_2NH_2) \cdot [Zn_2L] \cdot 3.5DMF$ ($H_5L = 2,5$ -(6-(4-carboxyphenylamino)-1,3,5-triazine-2,4-diyl-diimino)diterephthalic acid).²⁵ Evidently, it is a big challenge to generate novel luminescent MOFs with these ligands to detect the NACs.

Herein, the semi-rigid ligand 4,4',4''-s-triazine-1,3,5-triyltri-*m*-aminobenzoate (H_3TATMA , Scheme 1) was utilized for self-assembly with inorganic Pr(III) ions. Acting as a functional organic ligand, H_3TATMA contains triazines as functional sites and $-COOH$ groups as coordinating sites. Interestingly, the solvothermal reaction generates a 2D luminescent MOF (namely **1**) with the *kgd* topology. The resultant sample was able to detect NACs, especially TNP, *via* luminescent quenching.

Experimental

Materials and methods

All solvents and chemical reagents for syntheses were purchased from commercial sources and used without purification. H_3TATMA was successfully prepared according to the reported literature.¹⁵ Room-temperature powder X-ray diffraction (PXRD) spectra were obtained using a Rigaku D/Max-2500 diffractometer with a Cu-target tube ($\lambda = 1.5418 \text{ \AA}$) at 40 kV and 100 mA in the 2θ range from 4 to 40° . Thermogravimetric analyses (TGA) were conducted using a Perkin-Elmer TGA thermogravimetric analyser at the heating rate of $10^\circ \text{C min}^{-1}$ in the range of 30–800 $^\circ \text{C}$ under an air flow. Elemental analyses (C, H, and N) were conducted using a Perkin-Elmer 240 analyzer. Fourier-transform infrared spectra (FT-IR) were obtained *via* a Nicolet Impact 410 FT-IR spectrometer using KBr pellets in the range of 4000–400 cm^{-1} . All room-temperature luminescent measurements were performed using a Fluoromax-4 spectrofluorometer. All liquid UV-vis data were obtained using a UV-2450 machine.

Anal. calcd for $C_{60}H_{66}O_{20}N_{16}Pr_2$: C 44.67, H 4.09, N 13.90%; found: C 44.75, H 4.17, N 14.01%.

X-ray structure determination and structure refinement

The crystallographic data for **1** was obtained using a Bruker SMART APEX II CCD with Mo- $K\alpha$ radiation ($\lambda = 0.71073 \text{ \AA}$) at room temperature. The SADABS program was applied to correct the incident and diffracted absorption effects.²⁶ The structures were successfully solved by the direct methods and further refined by the full matrix least-squares against F^2 values using the SHELXTL package.²⁷ All the non-hydrogen atoms can be located from the Fourier maps and further refined by anisotropic thermal parameters. Since many disordered molecules exist in the structure of **1**, their corresponding diffraction data can be removed using the PLATON/SQUEEZE route.^{28,29} The solvent molecules were determined from the TGA data and elemental analyses (C, H, and N). The crystallographic data and structure processing parameters for **1** are summarized in Table 1, and the selected bond lengths and bond angles are listed in Table S1.[†]

Results and discussion

Crystal structure

Single-crystal X-ray diffraction analysis reveals that **1** crystallizes in the monoclinic *Cc* space group and exhibits a 2D layered structure with binuclear $\{Pr_2(COO)_6\}$ subunits extended by three-connected $TATMA^{3-}$ ligands. The asymmetric unit of **1** contains two crystallographically independent Pr^{3+} cations, two

deprotonated TATMA³⁻ ligands, and four coordinated oxygen atoms (Fig. S2†). As shown in Fig. 1a, the Pr1 cation is ten coordinated by seven oxygen atoms (Pr1–O = 2.494–2.807 Å) from four carboxylate groups of TATMA³⁻ ligands and three coordinated oxygen atoms. The Pr2 cation is bound with nine oxygen atoms (Pr2–O = 2.451–2.648 Å) from three chelating, two bridging carboxylate moieties of TATMA³⁻ ligands and one coordinated oxygen atom. The unique Pr1 and Pr2 ions are bridged *via* three carboxylate groups to form a binuclear {Pr₂(COO)₆} subunit. As shown in Fig. 1b, the TATMA³⁻ ligands show $\mu_1\text{-}\eta_1\text{:}\eta_1$, $\mu_1\text{-}\eta_1\text{:}\eta_1$, and $\mu_2\text{-}\eta_1\text{:}\eta_2$ coordination modes in mode I, and $\mu_1\text{-}\eta_1\text{:}\eta_1$, $\mu_2\text{-}\eta_1\text{:}\eta_2$, and $\mu_2\text{-}\eta_1\text{:}\eta_2$ coordination mode II. Moreover, the ratio of the two coordination modes in **1** is 1 : 1 (mode I:mode II). Each TATMA³⁻ ligand is connected to three {Pr₂(COO)₆} subunits to generate a 2D layer. The different layers can be further packed together in an ABAB fashion (Fig. 1c). Topologically, the {Pr₂(COO)₆} subunit and TATMA³⁻ ligand can be considered as 6-connected and 3-connected nodes, respectively. Thus, **1** can be simplified into a 3,6-connected *kgd* topology with the Schläfli symbol of (4³)₂(4⁶·6⁶·8³) (Fig. 1d).^{22,30}

FT-IR spectra, PXRD, TGA analysis

The FT-IR spectra of **1** exhibit strong and broad bands at 3422 cm⁻¹, which should be attributed to the stretching vibrations of –OH. The characteristic peak at 1694 cm⁻¹ in the organic ligand H₃TATMA should be ascribed to the carbonyl asymmetric stretching band (C=O) of –COOH. However, this characteristic peak at 1694 cm⁻¹ is not present in the spectrum of **1**; this implies that all the carboxyl groups of the ligand are deprotonated. The characteristic multiple bands for the asymmetric (ν_{as}) and symmetric (ν_{s}) stretching vibrations of the carboxylate group are observed between 1654 and 1402 cm⁻¹, and their different separations ($\Delta\nu = \nu_{\text{as}} - \nu_{\text{s}}$) suggest the various coordination modes of the carboxylate groups (Fig. S1†). In addition, the room-temperature PXRD patterns of the

resultant crystals of **1** demonstrate the phase purity of a large number of crystal samples (Fig. S3†). Furthermore, the PXRD patterns analyses indicate that **1** can retain high crystallinity after being soaked in DMF and kept in air for one week; this suggests that the layered structure possesses good stability (Fig. S3†). The TGA data of the crystals of **1** (Fig. S4†) exhibits a slow weight loss of 23.32% before 250 °C, which corresponds to the loss of guest molecules (calculated to be 23.68%). The framework starts to collapse and decompose with an increase in temperature. The residue is Pr₂O₃ (expt: 20.32%; calcd: 20.42%).

Luminescent and sensing properties

The solid luminescent properties of the free H₃TATMA ligand and **1** were determined at room temperature. The excitation and emission spectra of crystals of **1** dispersed in DMF were studied and have been discussed because it is insoluble and retains its structure in DMF well. It exhibits an excitation band at 292 nm, and displays luminescence with an emission band at 350 nm (Fig. 2a). In contrast, the maximum excitation and emission wavelengths of the H₃TATMA ligand in DMF are at 357 nm and 426 nm, respectively (Fig. 2b). These results indicate that the luminescent property of **1** is mostly attributed to the emission of the organic linker. The spectral blue-shift is mainly due to the coordination of the TATMA³⁻ ligand to the central Pr³⁺ ion. It leads to less vibrations of the skeleton and reduces the loss of energy *via* radiationless decay of the intraligand emission excited state.^{31,32}

To investigate the luminescent sensing ability of **1**, the emission spectra of the ground crystal powder of **1** dispersed in DMF with 600 ppm of different analytes were obtained under excitation at 292 nm due to its insolubility and highly luminescent intensity in DMF (Fig. 2c). It is noteworthy that the luminescent intensities of **1** are significantly dependent on the different solvents. Interestingly, **1** exhibits significant luminescent quenching behaviour in nitrobenzene (NB).^{33,34} To further monitor its luminescent response to NB, **1** was titrated with NB

Fig. 1 (a) Binuclear {Pr₂(COO)₆} subunits viewed as 6-connected nodes. (b) Two coordination modes of TATMA³⁻ ligands viewed as 3-connected nodes (hydrogen atoms are omitted for clarity and C, gray; O, red; N, blue; and Pr, green) (c) view of the 2D networks packed together in the ABAB fashion. (d) Simplified 2D coordination framework with the Schläfli symbol of (4³)₂(4⁶·6⁶·8³).

Fig. 2 Excitation (dot lines) and emission (solid lines) spectra of the free H₃TATMA ligand (a) and 1 dispersed in DMF (b). (c) Luminescent intensity of 1 crystal powder after immersing in DMF with 600 ppm of different analytes for about 2 minutes at room temperature upon excitation at 292 nm. (d) The emission spectra of 1 titrated with NB in DMF for about 2 minutes. 4.0 mg of 1 crystal powder was dispersed in 3.0 mL DMF.

at different concentrations in a DMF solution at room temperature (Fig. 2d). The results show that the emission intensity of 1 decreases continuously with an increase in NB concentration.

As discussed above, the luminescent quenching behaviour of the resultant sample is mainly related to the electron-withdrawing $-\text{NO}_2$ group. Hence, we further investigated the luminescent quenching behaviour of 1 to detect a series of NACs including 1-iodo-4-nitrobenzene (I-NB), 1,3-dinitrobenzene (1,3-DNB), and TNP. The luminescent quenching behaviour was monitored by luminescence spectroscopy ($\lambda_{\text{ex}} = 292 \text{ nm}$) when different amounts of analytes were added to the DMF solution (Fig. S5[†]). As shown in Fig. 3 and S6[†], the results indicate that TNP is the most effectively detected NAC due to the presence of three nitro groups in it. With an increase in the amount of $-\text{NO}_2$ groups, electron transfer becomes much easier; this leads to a more effective luminescent quenching performance.^{35–37} Moreover, there is a considerable degree of overlap between the absorption band of TNP and the emission spectrum of 1 in DMF (Fig. S7[†]). In addition, the N atoms in the TATMA³⁻ ligand can provide hydrogen-bonding interactions with the highly acidic phenol group ($-\text{OH}$) of TNP. The hydrogen-bonding interactions play an important role as electron-transfer bridges to improve the high selectivity of TNP.^{34–36} As abovementioned, the nature of the quenching mechanism may be mainly attributed to a combination of multiple factors including competitive absorption, electron transfer, and hydrogen-bonding interactions. However, further research is still needed to confirm the accurate process. As shown in Fig. S3[†], the PXRD results exhibit that the original framework of 1 is still well retained after the testing experiments for the NACs.

The corresponding quenching efficiency is quantitatively given by the Stern–Volmer equation: $I_0/I = 1 + K_{\text{SV}}[Q]$, where I_0 is the origin luminescent intensity without any analyte, I is the

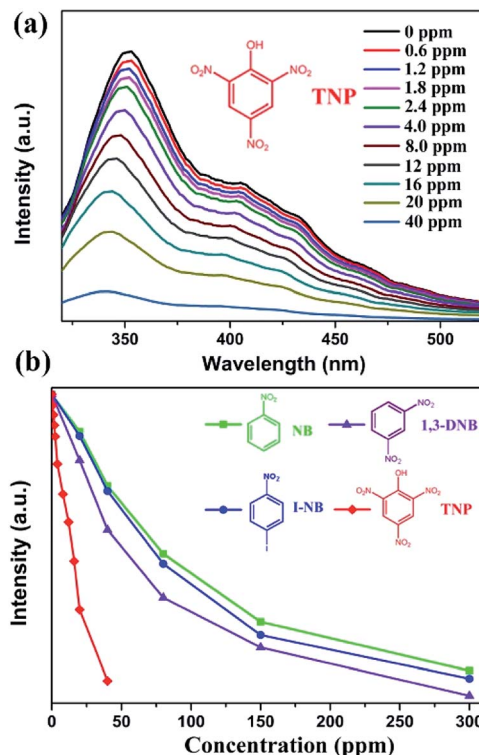

Fig. 3 (a) Emission spectra of 1 titrated with TNP in DMF for about 2 minutes. (b) Relationship between the emission intensities and the corresponding concentrations for NB (green), I-NB (blue), 1,3-DNB (violet) and TNP (red).

corresponding luminescent intensity after the addition of different amounts of the analyte as quencher, $[Q]$ is the molar concentration of the quencher, K_{SV} is the Stern–Volmer constant. If the plots of I_0/I vs. $[Q]$ plot are approximately linear, the Stern–Volmer constant (K_{SV}) can be determined precisely. The corresponding Stern–Volmer plots for all the NACs are almost linear at low concentrations (Fig. S8[†]), but the subsequent plots deviate from linearity at higher concentrations (Fig. S9[†]). This performance may be caused by the self-absorption phenomenon.^{38–43} The Stern–Volmer constants (K_{SV}) are $4.1 \times 10^3 \text{ M}^{-1}$ for NB, $5.0 \times 10^3 \text{ M}^{-1}$ for I-NB, $6.1 \times 10^3 \text{ M}^{-1}$ for 1,3-DNB, and $1.6 \times 10^4 \text{ M}^{-1}$ for TNP. As shown in Table 2, the corresponding K_{SV} of TNP is higher than those of some previously reported MOFs such as $[\text{Eu}_2(\text{L}_1)_{1.5}(\text{H}_2\text{O})_2\text{EtOH}] \cdot \text{DMF}$ ($2.0 \times 10^3 \text{ M}^{-1}$),⁴⁴ $[\text{Eu}_2(\text{TDC})_3(\text{CH}_3\text{OH})_2] \cdot \text{CH}_3\text{OH}$ ($1.1 \times 10^4 \text{ M}^{-1}$),⁴⁵ $\text{Zn}_2(\text{H}_2\text{L})_2 \cdot (\text{Bpy})_2(\text{H}_2\text{O})_3 \cdot \text{H}_2\text{O}$ ($1.36 \times 10^4 \text{ M}^{-1}$),⁴⁶ and $[\text{Cd}(\text{IPA})(\text{L})] \cdot (\text{DMA})_2 \cdot (\text{H}_2\text{O})_4$ ($2.5 \times 10^4 \text{ M}^{-1}$)⁴⁹ and $[\text{Tb}(\text{L})_{1.5}(\text{H}_2\text{O})] \cdot 3\text{H}_2\text{O}$ ($7.47 \times 10^4 \text{ M}^{-1}$).⁵⁰

The excellent sensing performances of 1 in suspension elicit widespread interest in detecting trace NACs in the vapour state at room temperature. Among the four NACs, liquid NB has highest vapour pressure as compared to the three solid NACs at room temperature.⁵¹ Hence, we applied a thin film device to implement the real-time solid–gas monitoring of NB vapour at

Table 2 A comparison of MOF-based luminescent probes for the detection of TNP^a

^a L₁ = 5,5'-(carbonylbis(azanediyl))diisophthalate, TDC = thiophene-2,5-dicarboxylate, Bpy = 4,4'-bipyridine, L₂ = 3-pyridylcarboxaldehyde nicotinoylhydrazone, IPA = Isophthalate, bpydb = 4,4'-(4,4'-bipyridine-2,6-diyl)dibenzoate, hbhdp = 4-(2-hydroxy-3-methoxybenzylidene-hydrazinocarbonyl)-N-pyridin-4-yl-benzamide, L₃ = 2-(2-acetoxy-propionylamino)-terephthalate, H₂bdc = 1,4-dicarboxybenzene, H₂bdc-NH₂ = 2-aminoterephthalic acid, DMF = N,N'-dimethylformamide, DMA = N,N'-dimethylacetamide.

room temperature.⁵² As shown in Fig. 4a, the emission intensity of **1** decreased continuously with an increase in exposure time under NB vapour. In addition, the corresponding quenching efficiency (%) was determined using the formula: $(I_0 - I)/I_0 \times$

Fig. 4 Time-dependent emission spectra (a) and the corresponding luminescent quenching percentage (b) after exposure of **1** to NB vapour at room temperature.

Fig. 5 Cycling tests of **1** dispersed in DMF with or without 600 ppm NB.

100%, where I_0 and I are the maximum emission intensities of **1** before and after exposure to NB vapour, respectively. As illustrated in Fig. 4b, NB can quench the emission intensity to 91.9% after an exposure time of about 500 s. The quenching phenomenon of **1** in the vapour state is similar to the liquid sensing process; this demonstrates that the quenching mechanism is based on the nature of the resultant sample.⁵³

Furthermore, it is very important to separate and recycle the crystal sample after use. In fact, **1** can be recycled by centrifuging the dispersed solution after use and washing several times with DMF. As shown in Fig. 5, the luminescent intensity and quenching ability of **1** exhibit very little change after five cycles. Furthermore, the high stability of the recovered sample is demonstrated *via* the PXRD patterns (Fig. S3†).

Conclusion

In summary, a luminescent 2D MOF was successfully synthesized based on the semi-rigid tritopic ligand H₃TATMA with triazines as functional sites and -COOH groups as coordinating sites. The resultant sample displayed fast and reversible solid-state detection of NAC. In addition, the corresponding K_{SV} values are $4.1 \times 10^3 M^{-1}$ for NB, $5.0 \times 10^3 M^{-1}$ for I-NB, $6.1 \times 10^3 M^{-1}$ for 1,3-DNB, and $1.6 \times 10^4 M^{-1}$ for TNP. We anticipate that this study provides a new avenue to obtain new structures using these functional semi-rigid ligands and opens a promising approach to design MOF-based sensors for NCAs in the future.
