D–A– π –A organic dyes with tailored green light absorption for potential application in greenhouse-integrated dye-sensitized solar cells†

Alessio Dessi,^{ID}*^a Dimitris A. Chalkias,^b Stefania Bilancia,^c Adalgisa Sinicropi,^{ID}^{acd} Massimo Calamante,^{ID}^{ae} Alessandro Mordini,^{ae} Aggeliki Karavioti,^b Elias Stathatos,^{*b} Lorenzo Zani,^{ID}^a and Gianna Reginato^{*a}

In this paper, we present the design and synthesis of three organic dyes specially developed for the fabrication of dye-sensitized solar cells for application in greenhouses cladding. The dyes (BTD-DTP1–3) are based on a benzothiadiazole (BTD)–dithienopyrrole (DTP) scaffold, and were assembled by using direct arylation reactions, allowing significant reduction of the number of synthetic and purification steps compared to classic cross-coupling procedures. Thanks to their structural design, the dyes absorb light in the green part of the visible spectrum while allowing good transmittance in the red and blue regions, thus ensuring high compatibility with light absorption by plants. Dye-sensitized solar cells built with the three dyes provided energy conversion efficiencies (ECEs) comparable or even superior to those obtained with the reference Ru-based dye N719, especially when using a thin and semitransparent TiO₂ layer (up to 8.77%). The photovoltaic performances are discussed considering the need to reach the best compromise between good ECE values and high levels of weighed transparency against the main plant photoreceptors.

Introduction

The efficient utilization of renewable energy sources is a major scientific challenge and probably the only option available to our society to meet the ever increasing global energy demand and simultaneously reduce CO₂ emissions and global warming.¹ In this context, conversion of solar light is particularly important, as it is abundant, widely distributed, free and practically inexhaustible,² as confirmed by the progress of photovoltaic (PV) technology and the continuous increase in its global installed capacity (12% increase of the solar PV market in 2019).³ However, there is still a huge need to further improve energy production from the sun. To achieve this goal, the

development of new PV technologies and the extension of the existing ones to novel applications can play a decisive role.⁴ Following this approach, integration of PVs into agricultural settings such as greenhouses, also known as “agrivoltaics”,⁵ recently became a relevant subject of research, aimed at combining the exploitation of renewable energy with the enhancement of food production and quality.^{6,7} However, almost all PV installations on greenhouses worldwide are made with conventional silicon-based modules, which is not advantageous because they are opaque and thus prevent light transmission, hampering plant growth and crop productivity. As a matter of fact, it was estimated that the roof coverage by crystalline Si-modules should not exceed 30%,^{8–10} a value which is even lowered to 10% for crops of high economic value, or in cases where food yield should be prioritized.^{11,12}

New generation photovoltaics such as organic solar cells (OSCs)^{13–15} or dye-sensitized solar cells (DSSCs)^{16,17} might be a valid alternative to overcome this drawback.^{18,19} The latter, in particular, can represent an ideal solution because they can be layered on glass or plastic, giving coloured, lightweight and transparent devices,^{20,21} able to work under a wide array of lighting conditions, without suffering from angular dependence of incident light.²² A DSSC is an electrochemical device that uses dye molecules adsorbed on a nanocrystalline semiconductor (generally TiO₂) to harvest sunlight and generate electricity.²³ Thanks to photo-excitation, at the anode an electron is promoted from the HOMO of the dye to its LUMO, and then transferred to the conduction band of the semiconductor.

The original state of the dye is then restored by electron donation from a redox mediator. In the meantime, the electron travels through the external circuit (generating an electric current) and is collected at the cathode, where the reduction of the oxidized redox mediator takes place. Obviously, the overall efficiency of the final device is strongly influenced by the sensitizer used and thus, especially in the context of agrivoltaics, there is a considerable innovation potential in the search of suitable dyes, potentially able to harvest incident light for electricity generation without adversely affecting plant growth. Indeed, it is well known that the “photosynthetically active region” (PAR), that is the region of the spectrum utilized by plants, is between 400 and 750 nm. However, not all light is converted with the same efficiency and two peaks occur in the blue (425–475 nm) and red (625–750 nm) regions of the visible spectrum,²⁴ corresponding to the area of activity of the most diffused forms of chlorophyll, *a* and *b*, as well as red and far-red phytochromes.^{25,26} For these reasons, the design of tailored sensitizers capable of absorbing visible light mostly in the green region, while transmitting blue and red wavelengths, can be a convenient approach to a greenhouse-integrated DSSC PV system, provided devices with moderate-to-good efficiency can be obtained. Such an approach has been already exploited in the field of organic solar cells containing near-IR absorbing polymer/acceptor blends,^{27–29} tandem photonic crystals,³⁰ and DSSCs. In the latter case, two examples using simple derivatives of the well-known Ru-based dye **N719**³¹ and a series of diketopyrrolopyrrole-derived organic dyes³² were described, the latter showing relatively low power conversion efficiencies ($\leq 2.24\%$).

More recently, we prepared a series of organic thiazolo[5,4-*d*]thiazole-containing sensitizers, **TTZ8–12** (Fig. 1) specifically designed for improving the light absorption capability in the green part of the visible spectrum while maintaining good transparency in the blue and red regions.³³ Such dyes were used to build semitransparent DSSCs, yielding 5.6–6.1% power conversion efficiencies. Dyes like **TTZ8–12** are based on push-pull D- π -A structures, in which a donor group (D) is connected to an acceptor/anchoring group (A) through a conjugated bridge (π , Fig. 1), and are common among metal-free dyes for DSSCs as they can be easily prepared and purified. Furthermore, their optical, electronic and electrochemical properties can be finely modulated by simple modifications of the D, π and A moieties.³⁴ To better refine such properties, it is also possible to introduce additional acceptor units between the donor and the π -spacer, leading to D-A- π -A dyes with optimal energy levels, extended spectral response, enhanced dye stability and excellent photovoltaic performances.³⁵

Aiming to disclose a new series of DSSC sensitizers for greenhouse integration, we decided to follow the latter approach and chose the well-known 2,1,3-benzothiadiazole (BTD) as an internal electron-accepting moiety, since it has already been shown to red-shift the UV-Vis absorption spectrum of the resulting compounds once introduced next to a donor group in a D-A- π -A structure.^{36–41} In addition, we chose the dithieno[3,2-*b*:2',3'-*d'*]pyrrole (DTP)³³ unit as the electron-donating group to be connected to BTD, since it had already

Fig. 1 Previously reported thiazolo[5,4-*d*]thiazole-based D- π -A photosensitizers **TTZ8–12**.

been successfully inserted in DSSC sensitizers presenting two main favourable features: it can be easily modified by introducing different substituents on the bridging nitrogen, allowing the tuning of important properties such as the solubility in organic solvents; it possesses a wide π -conjugation due to the co-planarity of its bridged tricyclic system. Thus, in this paper,

Fig. 2 Structure of the benzothiadiazole (BTD), dithienopyrrole (DTP) photosensitizers studied in this work.

Fig. 3 Energies and electron density distributions of the frontier orbitals of dyes BTD-DTP1–3 in THF solution.

we report the design and preparation of three new D–A– π –A organic photosensitizers, named **BTD-DTP1**, **BTD-DTP2** and **BTD-DTP3**, all containing the benzothiadiazole (BTD) scaffold and incorporating differently substituted dithieno[3,2-*b*:2',3'-*d*]pyrrole (DTP) π -linkers (Fig. 2).

In this series, compound **BTD-DTP1** is the simplest one, presenting only a small *n*-hexyl substituent on the dithienopyrrole nitrogen and a triphenylamine donor. Compound **BTD-DTP2** is decorated with a bulky biphenyl group flanked by *n*-octyloxy chains, which is expected to improve the compound solubility, as well as limit charge recombination phenomena in the cells after adsorption on TiO₂.⁴² Finally, dye **BTD-DTP3** is endowed with an additional benzene ring next to the anchoring group to further extend its conjugation length, influencing its spectroscopic properties. The three dyes have been electrochemically and spectroscopically characterized and used to build the corresponding DSSC and measure their photovoltaic performances.

Results and discussion

Computational studies

The structural and electronic properties of dyes **BTD-DTP1–3** were studied through computational investigations at the DFT and TD-DFT level, using the Gaussian 16, Revision C.01 suite of

programs.⁴³ Details of the methods used for the calculations can be found in the ESI.†

First, ground state optimized geometries were calculated for all dyes in vacuum (Fig. S2a†). It can be seen that the structures of dyes **BTD-DTP1** and **2** were very similar, with an almost planar backbone along the BTD–DTP–cyanoacrylic acid conjugated section, and a wider angle of approx. 34° between the BTD unit and the donor triphenylamine. Analogous features could be found for **BTD-DTP3**, although in that case a small angle of 13.4° was also seen between the DTP unit and the additional benzene ring, slightly affecting the overall conjugation of the molecule. Geometry optimization of the dyes was also carried out for the compounds adsorbed on TiO₂, using a Ti₁₆O₃₂ cluster as a model (Fig. S2b†), which has already been proven suitable for computing energies and molecular orbitals of organic dyes/TiO₂ systems.^{44–47} Results showed that the structures of compounds **BTD-DTP1–3** were barely changed upon anchoring on TiO₂, with the only exception of a significant planarization of compound **BTD-DTP3** along the DTP–benzene linkage (from 13.4° to 2.8°); this could cause a red-shift of the UV-Vis absorption spectrum of adsorbed **BTD-DTP3** compared to those of the other dyes (see below). In addition, in **BTD-DTP2–3**, the long alkoxy chains present on the biphenyl side group assumed an almost perpendicular orientation relative to the dye backbone, supporting the possibility of forming an efficient insulating layer on the semiconductor surface and suppress dye aggregation. The frontier orbital energies and electron density distributions were computed for the new dyes in THF solution (Fig. 3). All dyes presented HOMOs mostly located on the donor and central section of the molecules, with a strong contribution of the conjugated carbon scaffolds. Conversely, LUMOs featured a significant contribution of the acceptor portions of the dyes, together with the lone pairs of the heteroatoms (in particular those of the electron-withdrawing BTD unit).

In general, the frontier orbital shapes indicated a good degree of intramolecular charge transfer upon photoexcitation, together with a sizeable superposition of HOMOs and LUMOs on the central section of the molecules, which is typical of D–A– π –A dyes⁴⁸ and suggests the possibility of an intense light absorption *via* HOMO–LUMO transitions. In terms of orbital

energies, the values for **BTD-DTP1–2** were very similar, while the frontier orbitals of **BTD-DTP3** appeared slightly destabilized (approx. 0.1 eV), but still separated by approximately the same band-gap.

The computational study was completed by the assessment of the dye absorption and emission properties by TD-DFT calculations (see the ESI† for computational details), both in CHCl₃ and THF solution, as well as those adsorbed on TiO₂

(Table 1). Considering the excitation process, maximum absorption wavelengths ($\lambda_{\text{max}}^{\text{abs}}$) were computed above 510 nm for all dyes in solution, with a slight red-shift in CHCl₃ on account of the different solvent polarities, together with high oscillator strengths indicative of strong light harvesting by the dyes. These properties were also conserved after dye adsorption on TiO₂, in which case the $\lambda_{\text{max}}^{\text{abs}}$ values were even slightly higher: such absorption centred in the green region of the spectrum is

precisely what is needed for the planned application of the dyes in greenhouse-integrated DSSCs. In terms of transitions, for the dyes in solution, it seems that the main absorption peak was mostly due to the contribution of the HOMO–LUMO transition (69–75%), although this value decreased for the dyes adsorbed on TiO_2 (31–59%), as a result of the occurrence of transitions involving LUMO orbitals localized on TiO_2 . Concerning emissions, the computed values in THF revealed fluorescence maxima above 650 nm for all dyes, yielding relatively large Stokes shift values and pointing to a significant degree of structural relaxation following light absorption; oscillator strengths were also quite high, suggesting strong fluorescence intensity, although significant quenching was expected to occur after adsorption on the semiconductor. In conclusion, dyes **BTD-DTP1–3** might have highly suitable electronic and spectroscopic properties for the planned application in greenhouse-integrated DSSCs.

Synthesis of dyes BTD-DTP1–3

The key issue to solve to prepare BTD–DTP dyes was to find a simple and versatile synthetic approach, able to allow an easy scale-up, in view of their application in greenhouse buildings. To accomplish this goal, we modified the previously reported syntheses of BTD- and DTP-containing compounds,^{49–52} as depicted in Scheme 1. In particular, we planned to build the dye backbones by using direct arylation reactions, not requiring the use of any preformed organometallic reagent, to reduce as much as possible the number of synthetic and purification steps compared to traditional cross-coupling protocols. Accordingly, DTPs **1**,⁵³ **5** and **7**,⁴² and bromide **2**⁵⁴ were prepared following literature procedures. A possible convergent synthesis through the direct arylation of DTP-containing aldehyde **1** with bromide **2** was then investigated. The reaction was carried out in toluene, using $\text{Pd}(\text{OAc})_2$ and CataCXium A® as the precatalyst and ligand respectively, pivalic acid as an additive, and potassium carbonate as the base. Although the conversion of the starting materials was almost complete, the ¹H-NMR analysis of the reaction crude revealed the presence of a byproduct that was not completely detachable from the desired compound **3**, even after chromatographic purification. ¹H-NMR and ESI-MS analyses of a chromatographic fraction containing mainly the byproduct led to assigning its structure to the isomer **3-iso**

(Scheme 1, path a). Apparently, despite being in a sterically hindered position, the C–H bond in the 3-position of DTP **1** competes in the catalytic cycle with the more favored 6-position, probably because of the electron-withdrawing nature of the adjacent formyl group. Unfortunately, attempts to use different ligands, like $\text{P}(t\text{Bu})_3$, $\text{P}(\text{Cy})_3$, and XantPhos, or bases, like Cs_2CO_3 , did not improve the regioselectivity of the reaction.

Since the separation of **3** and **3-iso** was not possible, we abandoned the convergent synthetic pathway and prepared intermediate **4** through direct arylation of **1** with 4,7-dibromo-2,1,3-benzothiadiazole under our previously reported, optimized conditions (Scheme 1, path b).³³ In this case, improved regioselectivity was observed which, together with the successful separation of the two possible regioisomers by flash column chromatography, allowed us to recover pure aldehyde **4** in 39% yield. Finally, subjecting compound **4** to a classic Suzuki–Miyaura cross-coupling with *p*-*N,N*-(diphenylamino)phenylboronic acid easily allowed the placement of the triphenylamine group leading to compound **3**. Despite the problems observed in the direct conversion of **1** to **3**, the possibility of designing a C–H activation-based convergent synthesis for the **BTD-DTP2** dye was not abandoned *ex ante*, since we trusted that the higher steric hindrance of the biphenyl substituent in the 4-position of DTP **5** could prevent the C–H activation in 3-position. For this reason, we tested our optimized conditions of direct arylation by reacting DTP **5** with bromide **2**. As we expected, in this case, the C–H bond in 3-position was too hindered to react, thus only the right isomer was detected and the desired advanced intermediate **6** easily isolated in good yield (74%).

Finally, to gain access to aldehyde **8**, we performed a one-pot double arylation of DTP **7** using bromide **2** and 4-bromobenzaldehyde. The reaction was carried out using the optimized procedure that we previously reported for a different heterocyclic core.^{33,55} The desired advanced intermediate **8** was thus obtained in just one step, with 26% yield. It is noteworthy that neither a fresh catalyst nor an additive was added for the second C–H activation step with 4-bromobenzaldehyde, therefore both transformations could be promoted by the initial catalytic load. In addition, we determined that reversing the order of the addition of the two bromides did not affect the final yield. The moderate yield of the reaction was due to the formation of some co-products, which could not be entirely eliminated; details are provided in the ESI (Fig. S1†). Finally, all the advanced

intermediates **3**, **6**, and **8** were converted with high yields to the corresponding dyes **BTD-DTP1–3** through Knoevenagel condensations in an acidic environment (77–98%).

Spectroscopic and electrochemical characterization of dyes **BTD-DTP1–3**

A complete spectroscopic and electrochemical characterization of the dyes was performed and the corresponding data are reported in Table 2. UV-Vis spectra in CHCl_3 (Fig. 4a) and THF solution (Fig. 4b) were recorded showing, as expected, the maximum light absorption always located in the visible region, above 520 nm, and quite high molar attenuation coefficients ($4.95\text{--}6.43 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$). The differences among the spectra recorded in the same solvent were minimal (less than 10 nm), with a bathochromic shift in the order **BTD-DTP2** < **BTD-DTP3** < **BTD-DTP1**. As usual, a small solvatochromic effect was observed moving from one solvent to the other, with a 7–12 nm shift of the main absorption peak, which was probably due to differences in solvent polarity. Dyes **BTD-DTP1** and **BTD-DTP2**, which have the same direct connection between the cyanoacrylic acid and the dithienopyrrole unit, showed a shoulder peak at shorter wavelengths, partially covered by the main absorption, a feature that was not seen in the spectrum of **BTD-DTP3**. The spectroscopic characterization in THF solution was concluded by exciting all the dyes near their $\lambda_{\text{max}}^{\text{abs}}$ and recording the corresponding emission spectra (see Fig. S3†), which showed single-peak emissions located between 639 and 644 nm. Optical bandgaps (E_{0-0}) were estimated from the intersection of the normalized absorption and emission spectra, obtaining almost equal values between 2.08 and 2.11 eV, confirming the light-harvesting abilities of the compounds **BTD-DTP1–3** in the visible region. These values were almost equal to those obtained from the Tauc plots (see Fig. S4†), which were drawn starting from the UV-Vis data in THF solution. Such experimental data were in very good agreement with the results of the TD-DFT calculations presented above, with errors for the vertical excitation energies ≤ 0.11 eV in both solvents. Remarkably, comparable accuracy was also found for the fluorescence emission data in THF, with errors in the 0.02–0.04 eV range. This confirms the ability of TD-DFT calculations to efficiently

model the spectroscopic properties of donor–acceptor organic dyes, allowing us to focus the synthetic work only on the most promising compounds.

To depict a more realistic scenario of DSSC operating conditions, diffuse reflectance spectroscopy (DRS) and transmittance measurements were carried out on sensitized, thin (6 and 5 μm , respectively) and semitransparent TiO_2 films (analogous to those later used for the characterization of the solar cells), and are reported in Fig. 5. Two different solvents, THF (Fig. 5a) and chlorobenzene (CB, Fig. 5b), were used to prepare the dye solutions for staining the TiO_2 -based electrodes, and the spectrum of a corresponding system that employed the conventional **N719** dye dissolved in ethanol was also recorded, for comparison purposes. Transmittance measurements were performed on TiO_2 films sensitized with THF solutions of the dyes and are shown in Fig. 5c, where the two photosynthetically active regions are highlighted in cyan and red, respectively. Furthermore, the weighted transmittance (WT%) of the semitransparent films against the absorption spectra of the main plant photoreceptors, namely chlorophyll *a*, chlorophyll *b* and beta-carotene, was also calculated (see Table 2) to estimate the amount of photosynthetically active light approaching the plants after being filtered by the dyes (details of the calculations are reported in the Experimental section, see also Fig. S5†).

Clearly, on TiO_2 , the absorption peaks of the dyes were broader than in solution, but still located in the green region, at about 520 nm, while the absorption onset was found at about 700 nm, ensuring good transparency in the red portion of the visible spectrum, the most important one for the plant photoreceptors. Once again, this was in good agreement with the results of the above TD-DFT computational study. Compound **BTD-DTP3** showed a wide spectral window in the blue region too, making it a suitable candidate for application to greenhouses, as confirmed by transmittance measurements (Fig. 5c). Accordingly, its WT% value of 48% (Table 2) was the highest among the three sensitizers. In the spectra of the other two dyes **BTD-DTP1** and **BTD-DTP2** a shoulder is present at about 430 nm, which decreased the WT% values (17% and 37%, respectively). However, their stronger absorbance along the whole visible spectrum compared to dye **BTD-DTP3** suggested that

Fig. 4 UV-Vis absorption spectra of dyes **BTD-DTP1–3** (a) in CHCl_3 solution, (b) in THF solution.

Fig. 5 UV-Vis absorbance curves of the working electrodes of 6 μm thickness sensitized by the dyes **BTD-DTP1–3** (a) in THF and (b) in chlorobenzene (CB) solution and, for comparison, by **N719** in ethanol (EtOH) solution, obtained from DRS experiments. (c) Transmittance spectra of thin (5 μm) transparent TiO_2 films stained with THF solutions of dyes **BTD-DTP1–3**. Photosynthetically active regions are coloured in cyan (425–475 nm) and red (625–750 nm).

they could provide DSSC devices with superior photovoltaic performances.

Interestingly, the maximum light absorptions of dyes **BTD-DTP2** and **BTD-DTP3** remained almost unchanged moving from solution to TiO_2 adsorption, while **BTD-DTP1** exhibited a hypsochromic shift of 20 nm, becoming the dye with the most blue-shifted λ_{max} absorbance among the series. This behaviour could be due to the capability of the bulky bis-octyloxy-substituted biphenyl group of reducing the formation of H-aggregates in the solid state, which would be impossible for the smaller hexyl chain. Also, **BTD-DTP3** presented the most red-shifted absorption spectrum, which could be due to the attainment of a more planar structure upon anchoring on TiO_2 , as shown by DFT calculations (see above, and Fig. S2†). The density of adsorbed dyes on TiO_2 was then calculated by comparison with the absorbance of a standard solution of each dye in THF before and after sensitization; **BTD-DTP2** and **BTD-DTP3**, which have similar size, showed similar densities of $1.12\text{--}1.26 \times 10^{-7} \text{ mol cm}^{-2}$, while the smaller dye **BTD-DTP1** exhibited an approximately two-fold concentration ($2.48 \times 10^{-7} \text{ mol cm}^{-2}$) once adsorbed on a TiO_2 electrode.

Compared with THF, a more intense and broader absorption spectrum of the working electrode is attained by dissolving the dyes in CB, with the main differences to be observed in the 400–

450 nm and 600–650 nm regions. Besides, a small hypsochromic shift of all absorption peaks of the dyes was observed. These results were indicative of a higher loading of dye molecules on TiO_2 using CB instead of THF as a solvent, possibly accompanied by a modification of their self-organization on the semiconductor surface, as previously observed for other metal-free dyes.^{56,57} Interestingly, in both cases the working electrodes sensitized by the new organic dyes showed a quite higher absorbance in the visible spectrum when compared to that sensitized by the conventional **N719** (Fig. 5a and b). This shows the superior characteristics of dyes **BTD-DTP1–3** as sensitizers, arising from their high molar attenuation coefficients, which are more than threefold higher than that of the conventional **N719** in the visible range.⁵⁸

Finally, to estimate the oxidation potentials of the new dyes both at the ground and excited state, cyclic voltammograms (CV) of **BTD-DTP1–3** dissolved in CHCl_3 solution were recorded, using 0.1 M TBAPF₆ as the supporting electrolyte and ferrocene as the external standard (see Table 2). All the new molecules exhibited quasi-reversible first oxidation peaks (CV plots are reported in Fig. S6†). Ground-state oxidation potentials ($E_{\text{S}^+/\text{S}}$) were comprised in the +0.96 to 1.12 V vs. NHE range, and were thus much more positive than the potentials of the most common redox shuttles used in DSSCs, such as I^-/I_3^- .⁵⁹ Excited-

state oxidation potentials (E_{S^+/S^*}), on the other hand, were fairly negative (-0.99 to 1.12 V vs. NHE), ensuring a sufficient overpotential for facile electron injection into the conduction band of nanocrystalline TiO_2 ($E_{CB}(\text{TiO}_2) = -0.5$ V vs. NHE).¹⁶

Photovoltaic characterization of DSSCs built with dyes BTD-DTP1–3

Small-scale DSSCs of 0.25 cm^2 active area were fabricated using the new organic dyes and then fully characterized. Different

^a Values obtained as an average of the data collected on three devices and reported with the corresponding standard deviation.

anode thicknesses were tested, starting from an optimal value of 15 μm that is usually applied in conventional ruthenium-based DSSCs for attaining high performance.^{60–62} Then, in view of increasing the transparency of solar cells, two other series of DSSCs employing anodes of 9 μm and 6 μm thickness were studied. The different coloured working electrodes that were sensitized with the new dyes are shown in Fig. S7,[†] as well as a cross-section of the resulting solar cells. For the thinnest electrodes, CB was additionally tested as a dye-adsorption solvent and the results were compared with the corresponding systems fabricated using THF. In all cases, the results were also compared to those obtained by employing the conventional **N719** dye, under the same conditions. Fig. 6 shows the J - V characteristic curves of the DSSCs containing the different dyes, while their electrical characteristics are tabulated in Table 3.

Evidently, the solar cells built employing the **BTD-DTP** dyes were often better performing than those obtained with the conventional **N719** dye. In the case where the solar cells were fabricated using a 15 μm -thick photoanode, the energy conversion efficiency (ECE) of **BTD-DTP1**, **BTD-DTP2**, and **BTD-DTP3** was 8.12%, 8.06%, and 7.77%, respectively. These values are quite satisfactory when compared to that obtained with the conventional **N719** dye under the same conditions, which was 8.58%. The slightly reduced ECE attained in the case of the organic dyes was attributed to their lower V_{OC} and FF values, but, remarkably, they presented a consistently higher J_{SC} compared with **N719**. As the thickness of the photo-anode of DSSCs was reduced first to 9 μm and then to 6 μm , the solar cells fabricated with dyes **BTD-DTP1–3** still displayed very good performances, preserving a high ECE, which decreased less than 20% compared to that measured with the 15 μm -thick anode (in the worst case). In contrast, DSSCs built with **N719** dye showed a larger decrease in their ECE (higher than 30%) by reducing the photo-anode thickness, mainly attributed to the fall of the J_{SC} value, which could be ascribed to the lower molar attenuation coefficient of **N719** compared to those of **BTD-DTP1–3** ($1.33 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ for **N719**⁶³ vs. $4.95\text{--}6.43 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ for **BTD-DTP1–3**).

The efficiency values were even higher when the devices were fabricated using CB as a dye-adsorption solvent, with the record

ECE of the DSSCs reaching 8.77% with a 6 μm thickness. In particular, J_{SC} values obtained with the dye **BTD-DTP1** were higher than those recorded with the other two dyes, which is in agreement with its much higher adsorption density on TiO_2 , in turn linked to its smaller size (Table 2). On the other hand, V_{OC} values were higher for dyes **BTD-DTP2,3**, which could be related to their structure and in particular to the bulky biphenyl substituent featured on the DTP nitrogen (see below for a detailed discussion in the context of EIS experiments).⁴² To the best of the authors' knowledge, the ECE values obtained here are the highest reported for dyes especially developed towards greenhouse application,^{7,31–33,64} and compare well with those of the best sensitizers employed in semitransparent DSSCs,^{65–67} considering that the latter were not designed to comply with the same stringent spectral requirements. Remarkably, the increased ECE that was reached by using CB instead of THF as a dye-adsorption solvent was clearly related to a generalized increase of all the representative parameters of the solar cells, but in particular of the photocurrents (Table 3), probably as a result of the higher amount of dyes adsorbed on TiO_2 from the CB solution, as suggested by the broader and more intense light absorption profiles (see Fig. 5b). Despite the increased performances, this aspect should be carefully considered when evaluating the cell transparency requirements for application in greenhouses.

Fig. 7 shows the incident-photon-to-current-efficiency (IPCE) spectra and the corresponding integrated J_{SC} of the DSSCs with the 6 μm anode and sensitized by the different dyes. As can be seen, the solar cells built using organic dyes showed high external quantum efficiency in the visible spectrum, much higher than that of the solar cell fabricated using the conventional dye **N719**, with the photo-current onset being, in most of the cases, almost at 750 nm. The maximum IPCE was achieved with **BTD-DTP1** dye in DSSCs, which reached almost 80% at about 500 nm, while the **BTD-DTP2** and **BTD-DTP3** dyes reached 75% and 68%, respectively, in the visible spectrum. The use of CB as a dye-adsorption solvent instead of THF resulted in higher and broader IPCE spectra of the DSSCs, in agreement with the DRS results. In all cases, the external quantum efficiency of the DSSCs that employed the new organic dyes was

Fig. 7 Solid lines: IPCE curves of the solar cells that employed the working electrodes of 6 μm thickness sensitized by the different dyes. Dotted lines: Integrated short-circuit currents. (a) Sensitization from THF solution; (b) sensitization from CB solution.

much higher than that of the solar cell incorporating N719 dye, which did not exceed the value of 55% in the visible spectrum. This reveals the drawback of using the conventional N719 dye as a sensitizer in DSSCs employing thin photo-anodes and the superiority of our new organic dyes for the development of high-transparency solar cells. It should also be noted that the values of integrated J_{SC} coming from the IPCE measurements were in perfect agreement with the values stemming from the $J-V$ measurements, confirming the good accuracy of the photovoltaic characterization.

In the final part of this study, the charge transfer processes taking place in the solar cells were analysed by means of Electrochemical Impedance Spectroscopy (EIS).⁶⁸ Measurements were performed using cells with photoanodes of 6 μm thickness sensitized by the different dyes.

The Nyquist plots and the Bode phase diagrams are shown in Fig. 8, while the parameters obtained by EIS are tabulated in Table 4. In the Nyquist plots, due to the use of a high-performance liquid state electrolyte, two semicircles were observed; the small semicircle at the higher frequencies corresponds to charge transfer processes taking place at the Pt/electrolyte interface, while the larger one at the lower frequencies arises from the charge transfer processes taking place at the $\text{TiO}_2/\text{dye}/\text{electrolyte}$ interface.

Several parameters can be obtained by fitting the experimental spectra with an electrochemical model (see the equivalent circuit presented in Nyquist plots), namely the series resistance of the solar cell (R_s), the charge transfer resistance at the Pt/electrolyte interface (R_{Pt}), and the charge transfer resistance at the $\text{TiO}_2/\text{dye}/\text{electrolyte}$ interface (R_{rec}). Here, the values

Table 4 Parameters obtained from the EIS measurements of the solar cells that employed the working electrodes of 6 μm thickness sensitized by the different dyes^a

Dye	Solvent	R_{rec} (ohm)	τ_e (ms)
N719	EtOH	50	3.16
BTD-DTP1	THF	15	0.66
BTD-DTP1	CB	26	0.88
BTD-DTP2	THF	28	1.89
BTD-DTP2	CB	33	2.31
BTD-DTP3	THF	68	3.16
BTD-DTP3	CB	73	4.07

^a For $V = -V_{\text{OC}}$ under dark conditions.

of R_s and R_{Pt} were found to be comparable for all the DSSCs, reflecting the similar fabrication conditions and materials used at the counter electrode, while the values of R_{rec} were quite different. More specifically, the R_{rec} values increased in the order **BTD-DTP1** < **BTD-DTP2** < **BTD-DTP3**, both for THF and CB solutions. Such results suggest that for the latter two dyes a slower charge recombination rate is taking place at the $\text{TiO}_2/\text{dye}/\text{electrolyte}$ interface, in good agreement with their molecular structures. Indeed, it was already reported for other dyes that the bulky, alkoxy-substituted biphenyl substituent present on the DTP nitrogen might form an efficient protective layer on the semiconductor surface, resulting in an increased charge recombination lifetime compared to a simple alkyl chain, and thus in a higher V_{OC} .⁴² In addition, the values obtained when the staining was performed in CB were higher than the corresponding ones using THF, that is, once again, in agreement with a higher dye adsorption density, resulting in a more compact insulating layer on TiO_2 , able to slow down charge recombination. Considering the Bode phase plots, the frequency of the peaks observed in the middle-frequency domain can be used to evaluate the electron lifetime within the semiconductor (τ_e), providing another indication of the charge recombination rate taking place at the $\text{TiO}_2/\text{dye}/\text{electrolyte}$ interface.

In agreement with the previous measurements, the τ_e values increased in the order **BTD-DTP1** < **BTD-DTP2** < **BTD-DTP3**, both for THF and CB as dye-adsorption solvents, while the values obtained for the devices fabricated using CB as the staining solvent were higher than the corresponding ones with THF. Electron lifetime and charge recombination rate at the $\text{TiO}_2/\text{dye}/\text{electrolyte}$ interface appear thus to be influenced by factors such as dye molecule size and geometry, and dye adsorption behaviour, resulting in a strong influence on the photo-voltage of the solar cells, in agreement with previous literature reports.⁶⁹ Indeed, in the present investigation, the trend in the values of R_{rec} and τ_e found for the new BTD-DTP dyes was consistent with the values of V_{OC} obtained for the corresponding solar cells. In contrast the higher value of V_{OC} in the case of **N719**, compared with the other dyes, should be attributed to a different reason, considering that both its R_{rec} and τ_e values were intermediate between those of the BTD-DTP dyes. Indeed, for a certain electrolyte composition, differences

in V_{OC} are linked to variations in the quasi-Fermi-level of the metal oxide semiconductor, which is in turn correlated not only with the electron density at the equilibrium (depending on the rate of recombination between the semiconductor electrons and the oxidized electrolyte species), but also with the position of the semiconductor conduction band edge.¹⁶ It has been reported that, upon anchoring, charge transfer from the dyes to the semiconductor can induce a significant shift of the conduction band position, which is maximized in the case of compact dyes with a strong donating character.⁷⁰ **N719** is a homoleptic dye connected to TiO_2 through three carboxylate linkages,⁷¹ and is therefore expected to induce a higher shift in the semiconductor conduction band compared to BTD-DTP organic dyes, connected *via* a single carboxylic group and endowed with an additional electron-withdrawing unit, thus yielding devices characterized by a higher V_{OC} .

Conclusions

In this work, we presented the synthesis and characterization of three new D-A- π -A organic sensitizers, specially designed to build semitransparent DSSCs with potential application in agrivoltaics. The compounds are based on an electron-withdrawing 2,1,3-benzothiadiazole core connected to an electron-rich dithieno[3,2-*b*:2',3'-*d*]pyrrole (DTP) unit, but present different bulky side chains influencing their physico-chemical properties. Computational studies at the TD-DFT level suggested that the compounds should be able to absorb light intensely in the green part of the visible spectrum while leaving appropriate "windows" in the red and blue regions, making them suitable for the foreseen application.

Assembly of the dyes' central backbone was swiftly achieved by means of Pd-catalysed direct arylation protocols, which allowed significant reduction of the number of synthetic steps and purification procedures of the intermediates compared to classic cross-coupling reactions. UV-Vis absorption and transmittance studies of the synthesized dyes both in solution and those adsorbed on TiO_2 essentially confirmed the results of calculations. Fabrication of DSSC devices and measurement of their photovoltaic characteristics highlighted how the new organic dyes produced cells of comparable efficiency relative to the reference Ru-based dye **N719** when employing a thick TiO_2 layer, but largely overcame its performances when thinner (down to 6 μm) layers were used, making them more suitable for the fabrication of transparent devices. In addition, staining from CB solutions of the dyes was demonstrated to provide more efficient cells compared to the use of a more common solvent such as THF, probably thanks to the higher density of dye molecules adsorbed on the semiconductor surface. Under such optimized conditions, remarkable ECE values between 7.14 and 8.77% were obtained, with high photocurrents up to $>20 \text{ mA cm}^{-2}$. EIS studies revealed a close connection between the dye structures and the recorded photovoltages, indicating that the bulky biphenyl substituent present in dyes **BTD-DTP2**–**3** could screen efficiently the semiconductor surface and thus reduce charge recombination rates at the $\text{TiO}_2/\text{dye}/\text{electrolyte}$ interface. Clearly, finding the right compromise between these

two important properties will constitute the key to the successful development of large-area prototypes. These investigations are currently in progress and their results will be reported in due course.

Author contributions

A. D., L. Z., M. C., A. M. and G. R. conceptualized the work. A. D. and S. B. performed the synthesis and the photoelectrochemical characterization of the dyes. M. C. contributed to the NMR- and MS-characterization of the dyes. A. S. made the computational analysis. D. A. C., A. K. and E. S. fabricated and characterized the test solar devices. The manuscript was written through contributions of all authors. All authors have given approval to the final version of the manuscript.

Conflicts of interest

There are no conflicts to declare.
