# Interfacial complexation driven three-dimensional assembly of cationic phosphorus dendrimers and graphene oxide sheets†

Nadia Katir,<sup>\*a</sup> Anass Benayad,<sup>\*b</sup> Denis Rouchon,<sup>c</sup> Nathalie Marcotte,<sup>d</sup> Nabil El Brahmi,<sup>a</sup> Jean Pierre Majoral,<sup>e</sup> Mosto Bousmina<sup>a</sup> and Abdelkrim El Kadib<sup>\*a</sup>

High content nitrogen, sulfur and phosphorus heteroatoms assembled in tree-like dendrimers (DG<sub>n</sub>) are confined within the galleries of two-dimensional graphene oxide (GO). The presence of the ternary diethyl-*N*-ethyl-ammonium groups on the dendrimer peripheries ensures the exfoliation of graphene sheets thereby affording interfacially bridged, three-dimensional heteroatom-enriched graphene-based hybrid nanostructures (DG<sub>n</sub>-GO). Dendrimer generation (from 1 to 4) that reflects the bulkiness of these conceived nano-trees impacts increasingly the degree of dispersion-exfoliation and sheet disordering. The long-term stability of these aqueous suspensions associated with their handling flexibility allows uniform accommodation of the resulting hybrid materials as flame-retardants in bioplastics.

## Introduction

Peeling-off tiny graphene sheets, reported fourteen years ago,<sup>1</sup> have initiated an avalanche of investigations primarily focused on their massive production,<sup>2</sup> surface-functionalisation,<sup>3</sup> nanocomposite manufacturing<sup>4</sup> and their subsequent use for energy storage and conversion,<sup>5</sup> catalysis,<sup>6</sup> gas sensing,<sup>7</sup> and in nanomedicine and healthcare applications.<sup>8</sup> Owing to their fascinating properties, graphene-based materials stand as prominent contenders for future emerging nanotechnologies, specifically those tightly connected to flexible and wearable electronics.

Splitting tactoids or layered graphite stacks into individual, well-exposed thin carbon sheets is a fundamental prerequisite to access high-quality graphene materials.<sup>9</sup> The introduction of heteroatoms within these individual sheets by insertion, impregnation or covalent grafting allows for modulating further their physical and chemical properties.<sup>3</sup> Physical methods are

more relevant to produce high-quality graphene materials but are not, unfortunately, cost-effective because of the need for sophisticated apparatus and energy-associated procedures. Oppositely, the straightforwardness and versatility of liquid-phase synthesis provide a large library of chemically modified graphene materials.

Graphene oxide (GO), obtained by oxidation of graphite, is prone to dispersion in aqueous and liquid solvents and to chemical modification owing to the presence of polar, transformable oxygenated epoxides, alcohols, ketones and carboxylic acids.<sup>10</sup> Beyond its molecular-surface functionalisation, more sophisticated nanostructures including graphene oxide coated polymers and biopolymers, liposomes, DNA, polyoxometalate and other assembled graphene-based nanomaterials have been recently reported.<sup>11</sup> This hybridisation at the nanoscale brings novel reactivity to graphene sheets and substantially enhances their long-term dispersion and stability. Despite these achievements, further innovative investigations are necessary to assemble these tiny building-blocks into a rationally designed, functional three-dimensional architecture suitable for practical applications.

Having recently revealed many specific behaviours of dendrimers in materials science,<sup>12</sup> we envisioned that their supra-molecular association with graphene sheets could provide a *novo-design* concept for new functional hybrid materials.<sup>13</sup> Dendrimers differ from their linear polymer congeners by their defined size, shape and topology, molecular diversity from the core to the surface, tunable flexibility or rigidity depending on the spacer installed in their branching units, amphiphilicity, and their well-established “generation effect”.<sup>14</sup> More specifically, phosphorus dendrimers display some intrinsic features including their organic-inorganic character, their typically

hydrophobic cyclotriphosphazene core, and the high content of nitrogen, sulfur and phosphorus heteroatoms in their framework that impart them with excellent stability.<sup>15</sup> The presence of the phosphorus element allows accurate elucidation of the chemical functionalisation undertaken on the outer-sphere of these architectures.<sup>16</sup> Their ability to swell in polar solvents<sup>17</sup> provides access to hierarchically porous pockets that entrap enzymes and living-cells,<sup>18</sup> confine and stabilize nanoparticles<sup>19</sup> and prematurely convert amorphous bursts into discrete mesocrystals.<sup>12,20</sup> In a conventional medium, this latter phenomenon occurs commonly in the solid state under high temperature conditions.

Based on the aforementioned achievements and our own endeavours, we became interested in the secondary-structure of phosphorus-dendrimers as a potent efficient exfoliating medium and heteroatom provider for graphene materials. We herein report the liquid-exfoliation of graphene oxide by a set of terminated – ternary diethyl-*N*-ethyl-ammonium – phosphorus dendrimers. The choice of peripheral ammonium groups was dictated by their favourable interaction with epoxy, alcohol and carboxylic acid, which efficiently stabilize exfoliated sheets.<sup>21</sup> The assembled dendrimer–graphene oxide hybrid materials thus obtained were isolated and characterized. Their stability was disclosed and their reactivity with hydrazine as a reducing agent was also undertaken with a special emphasis to elucidate the chemical interactions occurring at the material interface. We also present the wrapping of these exfoliated sheets in a bio-based shell-waste polysaccharide for the preparation of thermally stable, functional phosphorus-based hybrid bioplastics.

## Results and discussion

### Preparation of DG<sub>*n*</sub>-GO

In our experiments, four different generations of cationic phosphorhydrazone dendrimers, denoted as DG<sub>*n*</sub> (*n* = 1–4), were used.<sup>22</sup> These dendrimers feature similar core (cyclotriphosphazene) and similar peripheral groups (ternary diethyl-*N*-ethyl-ammonium) but differ in their size (number of phosphorus layers) and the number of ternary ammonium groups (12 ternary ammoniums for DG<sub>1</sub>, 24 for DG<sub>2</sub>, 48 for DG<sub>3</sub> and 96 for DG<sub>4</sub>) (Fig. 1a).

Liquid phase exfoliation was performed by subjecting 40 mg of graphene oxide (GO) in 100 mL of water to sonication. A ternary diethyl-*N*-ethyl-ammonium-terminated dendrimer DG<sub>*n*</sub> was then added to the solution and the mixture was stirred for 24 hours at room temperature (see the Experimental section for details). It is noteworthy that immediate flocculation was observed with a significant expansion of the solution volume, typical of the interfacial polyionic complexation between the nanosheets and the cationic dendrimers.<sup>23</sup> The solution was then filtered by centrifugation and the precipitate was washed four times with water to remove any soluble, unreacted dendrimers before drying the resulting DG<sub>*n*</sub>-GO materials under vacuum at room temperature.

DRIFT analysis of the resulting dark green powder reveals a typical fingerprint of cationic phosphorus dendrimers (Fig. S2, ESI†). Accurate details were drawn from solid-state NMR

spectroscopy. While CP MAS <sup>13</sup>C NMR of the starting GO displays only three signals nearly at 59, 69 and 132 ppm, attributed respectively to C–O–C, CH<sub>2</sub>–OH and C=C,<sup>24</sup> well-resolved signals assignable to the dendritic skeleton are also observed for DG<sub>*n*</sub>-GO hybrid materials. The characteristic methylene appears at 8.7 ppm, the *N*-methylated one at 33 ppm, the adjacent CH<sub>2</sub>–CH<sub>3</sub> at 46 ppm and the aromatics between 122 and 133 ppm. A complete disappearance of the signal attributed to the epoxide groups in GO (at ~59 to 60 ppm) was observed, pointing out to the ring opening of the latter by nucleophilic species belonging to DG<sub>*n*</sub>.<sup>24</sup> A slight shift to high values was also observed for the signal belonging to graphenic CH<sub>2</sub>–OH from 68 to 71 ppm (Fig. S3a, ESI†), owing much probably to the proximal presence of heteroatoms or dynamic sliding of DG<sub>*n*</sub> at the carbon layers.<sup>24</sup> CP MAS <sup>31</sup>P NMR allows discriminating signals of the phosphorus core (~5 to 8 ppm) and the ones installed within the branches (~67 to 70 ppm). The *P*<sup>core</sup> versus *P*<sup>branch</sup> intensity in DG<sub>*n*</sub>-GO was inverted by increasing the dendrimer generation, consistent with their molecular structures (Fig. S3b, ESI†). X-ray diffraction (XRD) of the starting GO reveals a signal at a *2θ* value of 9.68° that reflects the basal distance (*d* = 0.91 nm) of the periodic layers. A shift to 6.81° was observed once subjected to DG<sub>1</sub> (the smallest, first generation phosphorus dendrimer), indicating a significant expansion of the galleries to *d* = 1.29 nm because of the intercalation of the dendrimer. No signal was observed for more bulky DG<sub>2</sub>, DG<sub>3</sub> and DG<sub>4</sub>, indicating complete delamination of the GO layers (Fig. S4, ESI†). During sonication, the high shear impact allows for expanding the basal distance where the adsorbed dendrimer on the graphitic surface constitutes the driving force for preventing the restacking of graphene sheets. As the process goes on, the strong chemical interactions occurring at the dendrimer–graphene oxide interface reduce the motion of sheets and provide enough stability to resist the capillary forces acting on their framework during water removal.

SEM and TEM analyses were undertaken to visualise these objects in the micro- and nano-scale domain. SEM reveals crumpled layers that are connected to each other to form continuous stacks of several tens of nanometers with smooth compact layers inside (Fig. 2a, b and S5a, ESI†). This aligned densification at the microscale can be rooted in the occurrence of both physical and chemical cross-linking between cationic dendrimers and negative GO sheets. Individual, separated or uncovered graphene layers are not observed indicating that in principle, all sheets are entangled by phosphorus dendrimers, resulting in three-dimensional hybrid materials. EDX mapping confirms the presence of phosphorus, nitrogen, and sulphur supplied from the starting dendrimers and their homogenous distribution through the whole material network (Fig. 2c). TEM analyses show that DG<sub>*n*</sub>-GO materials are built from transparent thin layers where the intimate self-assembly of the two building-blocks affords wrinkled and crumpled nanostructures (Fig. 2d). The presence of aligned tubular layers (300 nm to 2 μm in length and 8 to 12 nm in width) as revealed by HRTEM analysis indicates an extension of the self-assembly mechanism beyond the nanoscale level (Fig. 2e, f and S5b, ESI†). This result finds its

root in the dual role of the cationic dendrimer that acts both as an exfoliating medium and as a cross-linking agent owing to the presence of abundant reticular anchoring points on its periphery. A quite similar pattern was previously reported by assembling polyethylenimine and graphene oxide nano-architectures.<sup>25</sup>

The resulting solid materials can be re-dispersed in water and the precipitation–dispersion process can be repeated several times without graphene sedimentation or dendrimer leaching. UV-visible analyses of the suspended  $DG_n$ -GO hybrids display a holistic bond with maxima at 286–290 nm attributed to the corresponding dendrimer, with a tail extending to the visible region due to the presence of conjugated aromatics belonging to graphene oxide sheets (Fig. S6, ESI†).<sup>24</sup> Compared to native  $DG_n$  that displayed a wavelength maximum at 285 nm,

**DG<sub>n</sub>-GO** maxima of these materials were shifted to higher values with a significant broadening of the band that may indicate the presence of both covalent and physical interactions as well as free terminal groups within the dendrimer skeleton.

A significant improvement of the thermal stability was noticed for **DG<sub>n</sub>-GO** compared to the pristine **GO** as illustrated by their TGA profiles. For instance, the  $T_{40}$  corresponding to the loss of 40 wt% was shifted from 254 °C for **GO** to around 480 °C for **DG<sub>1</sub>-GO**, **DG<sub>2</sub>-GO** and **DG<sub>3</sub>-GO**. An impressive  $T_{40}$  of 502 °C was reached for **DG<sub>4</sub>-GO** (Fig. S11, ESI†).

### Preparation of **DG<sub>n</sub>-RGO**

Having ascertained the exfoliation of graphene oxide sheets by phosphorus dendrimers and the tight presence of the latter within the tectonic nanostructure, one important question was how the presence of phosphorus dendrimers affects the accessibility to the graphene surface during reduction. Although complete restoration of graphene from graphene oxide is quite impossible (even under forcing conditions),<sup>10,26</sup> reduced graphene oxide (**RGO**) displayed improved electrical conductivity and thermal and chemical stability, making the corresponding hybrid materials of strong interest.<sup>27</sup> With this in mind, we subjected **DG<sub>n</sub>-GO** aqueous suspensions to hydrazine treatment followed by filtration and extensive washing before drying the resulting solid materials under vacuum. At this stage, two experimental observations must be noted: (i) while the initial exfoliation step did not affect the dark green colour of the starting graphene oxide, a dramatic change to a more pronounced black material was noticed during hydrazine treatment; (ii) simultaneously, while **DG<sub>n</sub>-GO** flocculated in solution, significant volume shrinkage was observed during hydrazine treatment, strongly suggesting an alteration of the ionic interfacial complexation of the two building blocks. Similar to their parent materials, the resulting **DG<sub>n</sub>-RGO** solids can be isolated and re-dispersed in water with good temporal stability. The precipitation–dispersion cycle can be repeated at least five times without leaching of the dendrimer skeleton from the graphenic surface material. It should be noted that **DG<sub>1</sub>-RGO** provides the less-stable dispersion among the **DG<sub>n</sub>-RGO** series, which can be correlated with the smallest size of the starting dendrimer.

SEM and TEM analyses of **DG<sub>n</sub>-RGO** reveal a similar morphology to **DG<sub>n</sub>-GO** parent materials, although significant densification of layers and slight shrinkage of the network seem to occur during hydrazine treatment (Fig. 3a, b and S7a, ESI†). HRTEM analyses show elongated core–shell crumbled nanostructures of several hundreds of nanometers in length with an interior width of 24 to 54 nm covered outside by a dense layer of 6 to 8 nm (Fig. 3d–f and S7b, ESI†). Comparing the topology of **DG<sub>n</sub>-RGO** and **DG<sub>n</sub>-GO**, the variation concerns only the width and not the length of the elementary nanostructures. This reorganisation emanates probably from an interfacial folding of several elementary structures during hydrazine treatment; the reduction step is suspected to consume polar oxygenated groups and consequently minimise interfacial electrolytic complexation.

Fig. 3 Microscopic analysis of **DG<sub>4</sub>-RGO**. (a and b) SEM of **DG<sub>4</sub>-RGO**. (c and d) TEM and (e and f) HRTEM of **DG<sub>4</sub>-RGO**.

XRD reveals a slight decrease of the basal plane in **DG<sub>1</sub>-RGO** (from 1.29 nm to 1.04 nm) that can be explained by a decrease of the layer thickness during oxygen removal from the surface. The basal plane was still however high in **DG<sub>1</sub>-RGO** compared to native **GO** ( $d = 0.91$ ). The absence of any appreciable peak for **DG<sub>n</sub>-RGO** ( $n = 2$  to 4) ruled out any restacking of graphene sheets and confirmed the total disordering and exfoliation of graphene sheets in these materials (Fig. S4, ESI†).

### Chemical interplay at the **DG<sub>n</sub>-GO** and **DG<sub>n</sub>-RGO** interface

The interfacial chemical interplay was accurately examined by coupling a set of analytical tools including RAMAN, X-ray photon spectroscopy (XPS) and solid-state NMR spectroscopy.

MAS CP <sup>13</sup>C NMR of **DG<sub>n</sub>-RGO** revealed the first evidence for oxygen removal from the **GO** surface. A typical signal belonging to the graphene oxide at ~70 ppm completely disappeared as illustrated in the ESI (Fig. S3a, ESI†). MAS CP <sup>31</sup>P NMR of the four materials displays the two typical signals of the core and the branching units (respectively at 4.8 to 7.5 ppm and at 67 to 69 ppm) thereby indicating the intactness of the dendrimer skeleton during chemical reduction and precipitation–dispersion cycles (Fig. S3b, ESI†).

We further investigated the variation observed in Raman spectroscopy, where the D (associated with the order/disorder of the system) and G (an indicator of the stacking structure) bands are the dominant vibrational modes observed respectively at 1354 and 1601  $\text{cm}^{-1}$ .<sup>26,28</sup> The ratio of the intensities of the two bands (D/G) is often used to determine the overall stacking of the sheets, and high D/G ratios indicate a high degree of exfoliation/disorder (Fig. S8, ESI†). The intensity ratio of the starting **GO** increased from 1.15 to 1.25 when intercalated with **DG<sub>1</sub>** and to 1.36 for the full exfoliation reached in the case of the bulky **DG<sub>4</sub>-GO** dendrimer. The highest exfoliation and disorder caused by **DG<sub>4</sub>** are further supported by the appearance of a new D' band as a shoulder at 1619  $\text{cm}^{-1}$  (Fig. 4). Upon reduction, a further increase of the D/G ratio was observed for these materials compared to the starting **GO** (1.48 for **DG<sub>1</sub>-RGO**, 1.54 for **DG<sub>2</sub>-RGO**, 1.58 for **DG<sub>3</sub>-RGO** and 1.37 for **DG<sub>4</sub>-RGO**) consistent with previous literature.<sup>26</sup> Moreover, all these materials displayed an additional D' band characteristic of increased disorder. Such perturbation, not observed in the case of

Fig. 4 RAMAN analysis of DG<sub>4</sub>-GO (left) and DG<sub>4</sub>-RGO (right).

graphene oxide exfoliated ammonium-terminated chitosan,<sup>21</sup> indicates that more disordering was experienced in the case of ternary ammonium-terminated dendrimers owing to their increased globular and radial (instead of linear) size bulkiness. The unique structure of phosphorus dendrimers and the highest ramification on the external surface maximise its contact with graphene sheets. The highest entropy reached under these circumstances allows for performing both parallel and perpendicular exfoliation depending on the thermodynamically favourable conformation.<sup>29</sup> The non-variation of the D/G ratio in the special case of DG<sub>4</sub> before (1.36 for DG<sub>4</sub>-GO) and after hydrazine treatment (1.37 for DG<sub>4</sub>-RGO) while keeping the D' band indicates that the highest disorder was already reached during the dispersion step. The increased number of functional groups allows for the total consumption/binding of the dendrimer to the sheets and the significant wrapping of the graphene surface left few oxygenated groups accessible/available during hydrazine treatment. A negligible alteration (reduction) of the material surface was consequently observed in this case.

Insight into the DG<sub>n</sub>-GO and DG<sub>n</sub>-RGO interfacial interplay was gained by XPS analyses. Pristine graphene oxide displays signals of carbon deconvoluted at 284.4 (C=C/C-C), 286.5 (C-O) and 288.5 eV (C=O/COO) and a minor  $\pi$ - $\pi^*$  plasmonic related band at 289.6 eV. The oxygen binding signal appears at 532.2 eV. We note the presence of an S (2p) doublet at 168.3–169.5 eV, attributed to sulfonic or sulfate groups generated

during Hummer oxidation. In DG<sub>n</sub>-GO ( $n = 1, 4$ ), binding energies of carbon, nitrogen, oxygen, sulfur and phosphorus were observed. The C<sub>(sp<sup>2</sup>-sp<sup>3</sup>)</sub>/C-O ratio was increased with a decrease of the COO ratio and the  $\pi$ - $\pi^*$  indicative of a chemical reaction of peripheral ternary ammoniums with oxygenated groups as well as more disordering of carbon sheets because of their exfoliation (Table S1, ESI<sup>†</sup>). Oxygen binding shows two oxygen types, C-O and C-O-P bonding. Nitrogen also reveals two peaks at 398.9 eV of N-P and C-N and at 401.2 eV typical of quaternized nitrogen atoms. Sulfur (2p) spectra also confirm the presence of P=S fragments belonging to the dendrimers at 161.3–162.5 eV along with residual sulfonate at higher binding energies (168.3–169.5 eV). Phosphorus binding reveals a broad signal corresponding to both N<sub>2</sub>PO and N<sub>4</sub>PS at 132.4 and 133.8 eV (Fig. 5 and S9, ESI<sup>†</sup>). Lastly, chlorides (the counter ions of the ternary ammonium) remain on the material surface (with a binding energy of 197.0 eV) despite extensive washing of the material framework. However, its concentration is below the spectrometer sensitivity (0.1 at%).

Hydrazine treatment induces a significant alteration of the material-surface composition as substantiated by XPS and in full agreement with NMR and RAMAN analyses. Indeed, the C 1s peak at 284.4 eV becomes predominant, attributed mainly to carbon sp<sup>2</sup>, while C-O peaks appear only as a shoulder with C-N and COO consistent with the removal of oxygenated species from the surface. A significant change in the spectral shape of O 1s is noticed with C-O-P being more abundant compared to C-O related bonds. In the meantime, a significant NH<sup>+</sup> related peak intensity decrease is observed alongside with the removal of chloride and sulphate species from the material surface during hydrazine treatment. The remanence of the phosphorus signal indicates the non-alteration of the phosphorus environment upon reduction. The atomic ratio of the chemical species is provided in the ESI section (Table S1, ESI<sup>†</sup>) and the suggested mechanism is further discussed in detail (S10, ESI<sup>†</sup>).

In UV-visible spectroscopy, significant to lower values were observed for DG<sub>n</sub>-RGO with respect to the parent DG<sub>n</sub>-GO

Fig. 5 XPS analyses (from left to right: binding energy of carbon, nitrogen oxygen and phosphorus elements) of (a) DG<sub>4</sub>-GO and (b) DG<sub>4</sub>-RGO.

**Scheme 1** Chemical interplay occurring at the dendrimer–graphene oxide interface. See S10 in the ESI† for further discussion.

materials (for instance from 290 nm to 285 nm and from 290 nm to 279 nm for  $DG_2$ -RGO and  $DG_3$ -RGO, respectively). This shift indicates a significant alteration of the interfacial properties of  $DG_n$ -RGO compared to the starting  $DG_n$ -GO materials (Scheme 1).<sup>24</sup>

### CS@ $DG_n$ -(R)GO nanocomposite bioplastics

The stable exfoliation reached in these modified graphene sheets associated with their improved properties prompted their use as flame-retardant nano-fillers for soft-bioplastics. Among the various polymers suitable as film-forming matrices, we considered chitosan CS (a biodegradable glucosamine polymer derived from bio-waste generated in fishery plants, which is available in enormous quantity on earth) especially useful as a packaging material *e.g.* for healthcare, food and agriculture.<sup>30</sup>

Our bioplastic was prepared in two steps starting first by solubilising medium molecular weight chitosan in aqueous acidic solution followed by the addition of 3 wt% of the filler (GO,  $DG_n$ -GO, and  $DG_n$ -RGO) dispersed in aqueous solution. Casting of the mixture under air in a Petridish enables the formation of good-quality, crack-free films (Fig. 6). Interestingly, despite the bulkiness of the as-prepared nano-fillers, SEM analysis reveals excellent homogenisation of the film,

particularly for CS@ $DG_n$ -RGO materials that exhibit a smooth surface. No phase separation or filler aggregation was observed, which is an excellent preliminary result toward the rational design of functional, mechanically robust bioplastics.

Thermogravimetric analysis (TGA) allows monitoring the bioplastic degradation. Previously, we noticed the detrimental use of graphene oxide as a filler for bioplastics and evidenced that oxygenated groups catalytically accelerate the C–C bond scission of the biopolymer.<sup>21</sup> To our delight, we herein discovered that the degradation of chitosan was significantly delayed in the case of CS@ $DG_n$ -GO and even, substantial improvement was gained for CS@ $DG_n$ -RGO. In practical terms, the half weight degradation of chitosan denoted as  $T_{50}$  was measured to be 325 °C. Improvement of CS thermal properties was noticed by the use of  $DG_1$ -GO and  $DG_4$ -GO where  $T_{50}$  was found to be 340 °C and 345 °C, respectively. The performance was even pushed up for CS@ $DG_4$ -RGO where its  $T_{50}$  reached nearly 400 °C, corresponding to an impressive  $\Delta T$  of 75 °C with respect to non-modified bioplastics (Fig. S11, ESI†).

## Experimental

### Synthesis of $DG_n$ -GO and $DG_n$ -RGO materials

**$DG_n$ -GO.** 40 mg GO was dispersed in 100 mL  $H_2O$  by sonication and the dispersion was mixed with  $DG_n$  ( $n = 1$ , 71 mg;  $n = 2$ , 84 mg;  $n = 3$ , 93 mg;  $n = 4$ , 65 mg) and stirred at room temperature for 24 h. The mixture was filtered and the solid was washed several times with water and ethanol and finally dried under vacuum at room temperature.

**$DG_n$ -RGO.** 3 mL of hydrazine was added to a dispersion of  $DG_n$ -GO ( $n = 1$ , 17 mg;  $n = 2$ , 25 mg;  $n = 3$ , 27 mg;  $n = 4$ , 22 mg) in 40 mL  $H_2O$ . The mixture was stirred at room temperature for 24 h. The mixture was filtered and the solid was washed several times with water and ethanol and finally dried under vacuum at room temperature.

## Conclusions

In this contribution, high content heteroatoms (nitrogen, phosphorus, and sulfur) assembled in a tree-like dendritic

**Fig. 6** (a) Intercalation of  $DG_n$ -RGO within the fibrillary network of chitosan. (b) Aqueous dispersion of  $DG_4$ -GO and the resulting transparent CS@ $DG_4$ -GO film (top) and (d) the corresponding SEM analysis. (c) Aqueous dispersion of  $DG_4$ -RGO and the resulting transparent CS@ $DG_4$ -RGO film (top) and (e) the corresponding SEM analysis.

network are confined within the layered galleries of graphene oxide. The globular structure of cation-terminated dendrimers enables them to act both as an exfoliating medium and a cross-linking agent to afford novel-extended nanostructures with highly disordered carbon sheets. Hydrazine treatment allowed substantial surface alteration of the ionic interfacial complexation without restacking of the graphene layers. Stable dispersion was obtained and as a proof of concept, the resulting functional ink was used as a nano-filler for aqueous-phase processing of bioplastics where significant improvement of the thermal stability was noticed. Considering the molecular diversity of  $\text{DG}_n\text{-GO}$  and  $\text{DG}_n\text{-RGO}$  materials, their synergistic functionality and the promising use of phosphorus dendrimers themselves in nanotechnology, these results appear promising for the development of multifunctional and biologically active flame-retardant hybrid mats and bioplastics.
