## Radical docking–migration: a powerful strategy for difunctionalization of alkenes and alkynes

Zhu Cao,<sup>ab</sup> Fushan Chen<sup>b</sup> and Chen Zhu<sup>ib</sup>\*<sup>b</sup>

Radical-mediated difunctionalization of alkenes and alkynes represents a powerful and efficient strategy for constructing complex molecular architecture from simple unsaturated precursors. The docking–migration approach, which involves the initial addition of a radical species to an alkene or alkyne followed by intramolecular migration of a functional group, has emerged as a versatile and broadly applicable tactic. This review summarizes the achievements in this rapidly developing area, with a focus on the design of bifunctional reagents that enable the simultaneous incorporation of two functional groups *via* radical addition and migration cascades. The scope encompasses various migrating groups, including aryl, heteroaryl, alkynyl, oximino, alkenyl, and imino units, and highlights extensions to challenging unactivated alkenes and alkynes. The mechanistic insights, substrate scope, and synthetic applications of these transformations are discussed, underscoring the potential of the radical docking–migration strategy in modern synthetic chemistry.

## 1 Introduction

Alkenes and alkynes are among the most fundamental and versatile building blocks in organic synthesis, enabling the construction of complex molecular architecture through a wide array of functionalization reactions. Radical-mediated difunctionalization offers a powerful and step-economic approach to simultaneously introduce two functional groups across unsaturated carbon–carbon bonds, thereby rapidly increasing molecular complexity from simple precursors.<sup>1</sup> Despite significant advancements over the past several decades, the current synthetic methods remain largely constrained to activated alkenes that feature a neighbouring  $\pi$ -system, such as an aryl, carbonyl, or heteroatom, capable of stabilizing the transient alkyl radical intermediate through  $p$ - $\pi$  conjugation or heteroatom lone pair– $\pi$  interactions (Scheme 1a). Conversely, the difunctionalization of unactivated alkenes, including simple aliphatic olefins, continues to pose substantial challenges.

Radical-mediated difunctionalization of alkynes to access polysubstituted alkenes remains relatively underdeveloped.<sup>2</sup> This can be attributed to well-recognized kinetic and thermodynamic challenges,<sup>3</sup> including the high reactivity of vinyl

radical intermediates generated upon addition of extrinsic radicals to alkynes. These species often undergo undesirable rapid cyclization or addition to other  $\pi$ -systems, in addition to participating in fast intramolecular or intermolecular hydrogen atom transfer (HAT) processes. As a result, contemporary synthetic approaches still rely heavily on the use of activated alkynes, exemplified by phenylacetylene derivatives, where the resulting vinyl radical intermediates are stabilized through  $p$ - $\pi$  conjugation. By contrast, unactivated aliphatic alkynes, which lack such a stabilizing effect, present significant hurdles. Furthermore, free radical-mediated alkyne difunctionalization frequently yields alkene products as mixtures of *Z/E* isomers, thereby limiting the synthetic utility of these methods.<sup>4</sup>

To address these challenges, a breakthrough was achieved with the development of the “docking–migration” strategy, pioneered by our group.<sup>5,6</sup> Bifunctional reagents, bearing a radical donor (**D**) and a migratory group (**M**) connected *via* a linker, are readily synthesized in a few steps. The radical addition (docking) of **D** to the alkene/alkyne generates a radical intermediate that triggers the subsequent intramolecular migration of **M** (Scheme 1b). This strategically designed sequence effectively converts an intermolecular reaction into an intramolecular process, ensuring efficient difunctionalization with broad substrate compatibility. This strategy offers several distinct advantages over traditional three-component approaches. (1) It significantly expands the substrate scope, enabling the difunctionalization of challenging unactivated alkenes and alkynes. These substrates are often recalcitrant in conventional intermolecular radical processes due to polarity mismatches, unfavorable kinetics, or competing side reactions. (2) The intramolecular migration step proceeds through a cyclic transition state, which often imparts exceptional control over stereochemistry. Remarkably, for cycloalkenes, this renders kinetic control of stereoselectivity to generate the non-trivial *cis*-products. (3) By merging two coupling partners into a single, well-designed bifunctional reagent, the docking–migration approach enhances synthetic efficiency, minimizes byproduct formation, and improves atom economy.

This review summarizes the accomplishments in the radical-mediated difunctionalization of alkenes and alkynes *via* the docking–migration strategy. We discuss the development of various bifunctional reagents, featuring sulfone, tertiary alcohol, ether, sulfoximine, and ester structural motifs, which enable aryl, heteroaryl, alkynyl, oximino, alkenyl, and imino migrations. Notably, we also introduce the asymmetric docking–migration processes, which have unlocked novel, enantioselective pathways for alkene difunctionalization. The scope encompasses both activated and unactivated substrates, highlighting the versatility of this approach for the synthesis of complex molecules. Furthermore, we extend the discussion to alkyne difunctionalization, where functional group migrations have recently been applied to achieve stereo- and regio-selective transformations that were previously considered challenging.

## 2 Alkene difunctionalization

### 2.1 (Hetero)Aryl migration

In 2018, our group established the concept of radical docking–migration, achieving the photocatalytic difluoromethylative heteroarylation of alkenes using sulfone-based bifunctional reagents **1** (Scheme 2).<sup>6</sup> This method enables the efficient intermolecular fluoroalkyl radical addition followed by intramolecular heteroaryl migration, delivering valuable heteroaryl substituted alkyl difluorides **3**. Both activated and unactivated alkenes underwent smooth transformation under mild photocatalytic conditions, demonstrating broad substrate generality. The tetrabutylammonium iodide (TBAI) additive played a dual role as a reductant to turn over the photocatalytic cycle and as the halogen source incorporated into the final product. The design of the bifunctional reagents was crucial, allowing diverse

Scheme 2 Difluoromethylative heteroarylation of alkenes *via* docking–migration.

N-containing heteroarenes, including benzothiazole, pyrimidine, and quinoline, to be efficiently installed *via* the docking–migration process. Furthermore, the protocol was successfully applied to the late-stage functionalization of complex drug molecules and natural product derivatives, highlighting its potential for the rapid synthesis of structurally diverse compounds.

In the proposed mechanism, the Ir<sup>III</sup> photocatalyst is promoted to its excited state with visible light irradiation, which undergoes oxidative quenching by the C–Br bond of substrate **1**. This step affords the difluoromethyl radical **1-I** along with an Ir<sup>IV</sup> species. The resultant radical **1-I** adds across the alkene, yielding the alkyl radical intermediate **1-II**. Subsequently, this alkyl radical is captured intramolecularly by the benzothiazolyl group *via* a five-membered cyclic transition state, forming the spiro N-radical species **1-III**. Extrusion of SO<sub>2</sub> then delivers the difluoroalkyl radical **1-IV**. Concurrently, single-electron transfer from TBAI to the Ir<sup>IV</sup> species regenerates the ground-state Ir<sup>III</sup> catalyst and liberates iodine, which subsequently couples with radical **1-IV** to furnish the final difunctionalized product **3**. This sequence perpetuates the catalytic cycle, ensuring continuous turnover.

In the same year, Stephenson *et al.* reported a visible light induced aminoarylation of electron-rich alkenes using aryl-sulfonylacetamides **4** as bifunctional reagents, enabling the synthesis of 2,2-diarylethylamines with high *anti*-Markovnikov regioselectivity and good diastereoselectivity (Scheme 3).<sup>7</sup> This

redox-neutral transformation proceeds *via* a radical cation intermediate **4-I** generated through single-electron oxidation of an electron-rich alkene, followed by nucleophilic addition of **4** to generate intermediate **4-II** and a subsequent Smiles type 1,4-aryl migration to produce intermediate **4-III** or **4-IV**. Sequential interaction with the photocatalyst yields product **6**, while regenerating the photocatalyst. Conducted under mild conditions with concomitant release of SO<sub>2</sub>, the reaction exhibits good functional group compatibility. However, the scope of applicable alkenes and bifunctional reagents is largely limited.

The installation of a sulfonyl group could invert the inherent polarity of an alkyl radical, rendering it electrophilic and thereby enabling addition to electron-neutral or rich aliphatic alkenes. Following radical addition, the ensuing docking-migration cascade with concomitant SO<sub>2</sub> extrusion would ultimately regenerate the original alkyl group, thereby achieving a long-standing challenging radical alkylation of unactivated alkenes. In 2020, our group reported the radical alkylation of aliphatic alkenes by the docking-migration strategy using sulfone-based bifunctional reagents **7** (Scheme 4).<sup>8</sup> This strategy enables the concomitant introduction of an alkyl group and a heteroaryl moiety across a broad range of alkenes. The key design involves the generation of electrophilic sulfone-bearing alkyl radicals, thereby overcoming the polarity mismatch problem that typically hinders the radical alkylation of unactivated alkenes. Under mild photoredox conditions using *fac*-Ir(ppy)<sub>3</sub> as a photocatalyst and *tert*-dodecylthiol as both a hydrogen atom donor and reductant, the reaction proceeds efficiently to afford a wide range of valuable alkylated products.

Scheme 4 Polarity-umpolung radical heteroaryl-alkylation of aliphatic alkenes.

The method exhibits excellent functional group tolerance, accommodating sensitive functionalities such as free alcohol, epoxide, and aldehyde. Notably, the protocol is applicable to complex natural products and drug molecules, enabling late-stage functionalization. The proposed mechanism involves photoredox-induced generation of an electrophilic alkyl radical **7-I** from the bifunctional reagents. This radical adds to the alkene, forming intermediate **7-II**, which undergoes intramolecular heteroaryl or oximino migration *via* a cyclic transition state. Subsequent extrusion of SO<sub>2</sub> yields radical intermediate **7-IV**, which is then reduced by the thiol to furnish the final product and regenerate the thiol radical, thereby sustaining the catalytic cycle.

This polarity-umpolung protocol was extended to three-component radical alkylation of alkenes (Scheme 5).<sup>9</sup> This method simultaneously introduced a thioalkyl and a heteroaryl group across alkene. The reaction proceeds under mild photoredox conditions with *fac*-Ir(ppy)<sub>3</sub> as the catalyst and exhibits broad functional group tolerance, accommodating a wide range of styrenes, aliphatic alkenes, and complex alkene molecules. Key to the success is also the rational design of the sulfone-based bifunctional reagents, which initially generates an electrophilic alkyl radical **10-I** under photoreduction conditions. This radical adds regioselectively to the alkene, followed by intramolecular heteroaryl migration and SO<sub>2</sub> extrusion to form a new alkyl radical intermediate **10-IV**. This radical is then efficiently trapped by phenyl benzenethiosulfonate (PhSO<sub>2</sub>SPh) or analogous reagents, yielding the corresponding heteroaryl-substituted alkyl thioethers.

Scheme 3 Arylsulfonylacetamides as bifunctional reagents for the difunctionalization of electron-rich alkenes.

Scheme 5 Polarity-umpoling three-component radical alkylation of alkenes.

In 2021, our group reported the assembly of N-fused heteroarenes from alkenes using sulfone-based heterocyclizing reagents **13** (Scheme 6).<sup>10</sup> This method leverages the docking–migration process, followed by an intramolecular cyclization, to efficiently construct valuable heterocyclic scaffolds. Operating under simple copper catalysis, the transformation initiates *via* a single-electron transfer to generate an electrophilic alkyl radical **13-I** from the reagent. This radical adds regioselectively across the alkene substrate, triggering an intramolecular heteroaryl migration with concomitant SO<sub>2</sub> extrusion to form a new alkyl radical intermediate **13-IV**, which then abstracts a halogen atom from the solvent or the bifunctional reagent to form intermediate **13-V**. This adduct simultaneously undergoes intramolecular cyclization caused by a nucleophilic nitrogen atom from the migrated heteroaryl group, finally furnishing the N-fused heterocyclic product. The protocol accommodates a wide range of activated and unactivated alkenes with broad functional group tolerance. Furthermore, the modular design of the bifunctional reagents enables access to seven distinct types of N-fused heterocyclic cores.

A metal-free radical difunctionalization of ethylene was disclosed in 2023 (Scheme 7).<sup>11</sup> Operating under mild photocatalytic conditions, the method leverages a functional group migration strategy to achieve three-component heteroarylation of ethylene. The process begins with photolytic homolysis of the C–Br bond in the sulfone reagent, generating an electrophilic carbon radical **16-I** that preferentially adds to ethylene over electron-deficient heteroarenes. The resulting primary alkyl

Scheme 6 Assembly of heteroarenes *via* the docking–migration–cyclization cascade.

radical intermediate **16-II** undergoes rapid intramolecular migration of a heteroaryl group *via* a kinetically favored five-membered transition state, followed by SO<sub>2</sub> extrusion to form a nucleophilic radical **16-III**. This species is then trapped by a variety of N-heteroarenes in a Minisci-type reaction, delivering densely functionalized heteroarylated products with high selectivity and broad functional group tolerance. The strategy effectively suppresses competing ethylene oligomerization or polymerization, highlighting the power of radical docking–migration processes for the difunctionalization of the simplest alkene under metal-free conditions.

This protocol was further extended to a metal-free alkylheteroarylation of ethylene and other low-boiling-point alkenes using rationally designed sulfone-based bifunctional reagents **19** (Scheme 8).<sup>12</sup> The process is initiated by the visible-light-induced homolytic cleavage of a C–Br bond, generating an electrophilic alkyl radical **19-I** that adds to ethylene. This addition is followed by an intramolecular migration of a heteroaryl or oximino group *via* a kinetically favored five-membered transition state, with concomitant extrusion of SO<sub>2</sub> to form a nucleophilic radical **19-IV**. The resulting radical is then trapped by hydrogen atom transfer from a thiol, delivering diverse heteroaryl/oximino-substituted alkane products. Notably, the reaction proceeds efficiently without external photocatalysts or transition metals and is applicable to a range

Scheme 7 Three-component radical 1,2-difunctionalization of ethylene.

of gaseous and low-boiling-point alkenes. The method also allows for deuterium incorporation *via*  $D_2O$ .

In 2023, Hong *et al.* reported a photocatalytic desulfonylative carbonylation of alkenes using arylsulfonyl acetates **22** as bifunctional reagents (Scheme 9).<sup>13</sup> In the presence of an Ir-based photocatalyst, the deprotonated sulfonyl acetate species undergoes single-electron oxidation to generate an electrophilic  $\alpha$ -carbonyl radical **22-II**. This radical adds across an alkene to form a carbon-centered adduct **22-III**, which then undergoes intramolecular aryl migration *via* a Smiles type rearrangement, culminating in desulfonylation and simultaneous formation of two C–C bonds. This method allows the efficient incorporation of both aryl and ester groups across unactivated alkenes, providing direct access to valuable  $\gamma$ -aryl ester derivatives under mild photochemical conditions.

Liu *et al.* also disclosed the photoredox-catalytic alkylation of internal alkenes employing arylsulfonyl acetates **25** as bifunctional reagents (Scheme 10).<sup>14</sup> Under blue light irradiation with 4CzIPN as the photosensitizer, the deprotonated sulfonyl acetate species undergoes single-electron oxidation to generate an electrophilic  $\alpha$ -carbonyl radical. This radical adds across an alkene to form a carbon-centered adduct, which then undergoes an intramolecular Smiles rearrangement, leading to desulfonylation and simultaneous formation of C–C bonds. This cascade affords valuable  $\gamma$ -aryl substituted ester derivatives with high regio- and diastereo-selectivity and broad functional group tolerance. In the proposed mechanism, single-electron

Scheme 8 Radical alkyl-heteroaryl difunctionalization of low-boiling-point alkenes.

oxidation of the deprotonated arylsulfonyl acetate by the photoexcited 4CzIPN catalyst generates an electrophilic  $\alpha$ -carbonyl radical **25-I**, which regioselectively adds to the alkene, forming a benzylic radical intermediate **25-II**. Subsequent intramolecular *ipso*-radical addition *via* a Smiles rearrangement, facilitated by a favorable  $\pi$ - $\pi$  stacking interaction,

Scheme 9 Arylsulfonyl acetates as bifunctional reagents for alkene difunctionalization.

Scheme 10 Arylsulfonyl acetates as bifunctional reagents for the difunctionalization of internal alkenes.

delivers a cyclic spiro radical intermediate **25-III**. Fragmentation of this intermediate then results in extrusion of SO<sub>2</sub> and formation of a stabilized alkyl radical **25-IV**. Finally, single-electron reduction and protonation afford the ester product.

In 2024, Nacsa *et al.* reported a similar alkyl-(hetero)arylation of alkenes using alkyl-(hetero)aryl sulfones **28** as bifunctional reagents under photoredox conditions (Scheme 11).<sup>15</sup> Key to the process is the photoinduced generation of an electrophilic alkyl radical **28-I** from the sulfone reagent, which adds to the alkene to form a new C–C bond. The resulting carbon-centered radical **28-II** undergoes an intramolecular 1,4-(hetero)aryl migration *via* a radical Smiles rearrangement, followed by desulfonylation to forge the second C-(hetero)aryl bond. This method accommodates mono- to tetra-substituted alkenes, exhibits excellent diastereoselectivity in both cyclic and acyclic systems, and allows for the incorporation of primary and secondary alkyl groups, as well as N-heteroarenes.

Later, the same group disclosed a radical amino-(hetero)arylation of alkenes employing (hetero)aryl sulfonamides **31** equipped with an *N*-diphenyl-2,4,6-triazinyl (DPT) protecting group (Scheme 12).<sup>16</sup> This strategy overcomes chemoselectivity challenges associated with the oxidative instability of primary amino-(hetero)arylation products and the inherent decomposition pathways of *N*-acyl sulfonamidyl radicals prevalent in conventional protected systems. Under photoredox conditions utilizing a highly oxidizing acridinium-type photocatalyst,

Scheme 11 Radical alkyl-(hetero)arylation of alkenes.

deprotonation and single-photon oxidation of the *N*-DPT sulfonamide generates an electrophilic sulfonamidyl radical **31-I**. This nitrogen-centered radical adds across a broad range of unactivated simple alkenes, from mono- to trisubstituted, forging the initial C–N bond. The resultant alkyl radical **31-II** subsequently undergoes a desulfonylative radical Smiles rearrangement, facilitating a 1,4-(hetero)aryl migration to establish the key C-(hetero)aryl bond and deliver the protected amino-(hetero)arylation product. The rationally designed *N*-DPT group not only prevents product decomposition by raising its oxidation potential but also avoids the deleterious fragmentation that plagues carbonyl-based protecting groups, thereby enabling the successful radical cascade. The reaction exhibits

Scheme 12 Radical amino-(hetero)arylation of unactivated alkenes.

Scheme 13 Aryl sulfinamides as bifunctional reagents for alkene difunctionalization.

excellent functional group tolerance, good diastereoselectivity, and accommodates a wide array of N-heteroarenes, including pyridine, pyrimidine, and thiazole.

In 2024, Stephenson *et al.* introduced aryl sulfinamides as bifunctional reagents **34** for the radical aminoarylation of alkenes (Scheme 13).<sup>17</sup> Operating under mild photocatalytic conditions with a weakly oxidizing photocatalyst, the method enables the generation of a nitrogen-centered radical that adds to alkenes, forming C–N bonds. This initiation is followed by a desulfinative Smiles rearrangement, which facilitates aryl migration and forges a new C–C bond. The process proves applicable to a variety of unactivated alkenes. The transformation commences with the base-assisted deprotonation of sulfinamide **34**, yielding anionic species **34-I**. Subsequent single-electron oxidation converts **34-I** into nitrogen-centered radical **34-II**, which undergoes radical addition across the alkene to furnish intermediate **34-III**. Radical adduct **34-III** then participates in a Smiles rearrangement *via* a dearomatized spirocyclic intermediate **34-IV**. Subsequent rearomatization facilitates homolytic cleavage of the C–S bond, generating *N*-sulfinyl radical **34-V**. This species may either undergo direct homolytic dissociation or be reductively cleaved by the reduced-state photocatalyst, ultimately releasing SO and affording the corresponding amidyl radical or anion, which is protonated to yield the final product.

In 2025, our group reported the modular synthesis of alkyl fluorides *via* a radical decarboxylative–desulfonylative difunctionalization of alkenes (Scheme 14).<sup>18</sup> Employing  $\alpha$ -sulfonyl carboxylic acids **37** as bifunctional reagents under Ir-based photoredox catalysis, the method enables the generation

of alkyl radicals **37-III** *via* decarboxylation. These radicals add to both styrenes and aliphatic alkenes, forming a C–C bond. The resulting adduct undergoes a kinetically favored intramolecular heteroaryl migration *via* a radical Smiles rearrangement, accompanied by SO<sub>2</sub> extrusion, to forge a second C–C bond. The nucleophilic alkyl radical intermediate then abstracts a fluorine atom from Selectfluor to yield the final product. This process concurrently constructs two C–C bonds and one C–F bond with broad substrate scope, including complex molecules, highlighting the power of radical docking–migration cascades to access valuable fluorinated building blocks.

In 2021, our group disclosed a catalyst-free 1,2-arylheteroarylation of alkenes *via* the radical docking–migration process involving the cleavage of an inert C–C bond (Scheme 15).<sup>19</sup> The reaction utilizes tertiary alcohol-based aryldiazonium salts **40** as bifunctional reagents, without the need for any external photocatalyst or additives. The transformation is initiated by photoinduced homolysis of the diazonium salt, generating an aryl radical **40-I** that adds across the alkene. The resulting alkyl radical intermediate **40-II** then undergoes an intramolecular 1,5-heteroaryl migration, accompanied by cleavage of a stable C(sp<sup>3</sup>)–C(sp<sup>3</sup>) bond, to form a ketyl radical species **40-IV**. This reductive ketyl radical subsequently donates an electron to another molecule of the aryldiazonium salt, regenerating the aryl radical and perpetuating a radical chain cycle. Termination *via* deprotonation yields the valuable polyaryllkane product.

Scheme 14 Modular synthesis of alkyl fluorides *via* decarboxylative–desulfonylative difunctionalization of alkenes.

Scheme 15 Radical-mediated 1,2-arylheteroarylation of alkenes with tertiary alcohol-based aryldiazonium salts as bifunctional reagents.

The protocol tolerates styrenes and electron-deficient alkenes. The strategic design of the bifunctional reagent, which incorporates both the migrating heteroaryl group and the cleavable tertiary alcohol moiety, is crucial for enabling this cascade.

Subsequently, our group reported a photocatalytic carboarylation of alkenes *via* the cleavage of the inert C–O bond in diaryl ethers (Scheme 16).<sup>20</sup> This method employs arylbenzothiazolyloether-based diazonium salts **43** as bifunctional reagents, 4CzIPN as an organic photocatalyst, and ascorbic acid (AsC<sub>2</sub>H<sub>2</sub>) as a reductant. The transformation begins with the photo-reduction of the diazonium salt to generate an aryl radical **43-I**, which adds across the alkene to form an alkyl radical **43-II**. The resulting alkyl radical intermediate **43-II** then adds intramolecularly to the benzothiazolyl group. This addition triggers a 1,5-heteroaryl migration, which concomitantly cleaves the C(Ar)–O bond and generates the phenoxy radical **43-IV**. The H-abstraction by **43-IV** from ascorbic acid results in the corresponding carboarylation product (path a). Alternatively, radical **43-IV** can be reduced by the ascorbate monoanion to the corresponding phenolate, which undergoes subsequent protonation to afford product **45** (path b). The radical chain process may be initiated *via* one of two pathways: either the direct photolytic homolysis of **43** to afford aryl radical **43-I** under visible light, or the reduction of **43** to **43-I** by **43-V**.

Scheme 16 Intermolecular radical difunctionalization by docking-migration of arylbenzothiazolyloether reagents.

Subsequently, both pathways converge in the same docking-migration cascade to yield product **45**. The reaction is compatible with both activated and unactivated alkenes. The products feature two valuable handles: a phenolic OH group amenable to cross-coupling and a benzothiazolyl moiety that serves as a masked aldehyde, enabling extensive post-synthetic diversification.

*N*-Aminopyridinium ylides, which serve as precursors for generating amidyl radicals, have been successfully employed as bifunctional reagents for alkene difunctionalization. In 2020, Hong *et al.* reported the radical aminopyridylation of alkenes with C-2 regioselectivity employing *N*-aminopyridinium ylides **46** (Scheme 17).<sup>21</sup> A wide range of substituted pyridinium ylides proved compatible with the method, each affording the desired products in synthetically useful yields. This approach was amenable to styrenes and unactivated alkenes. Furthermore, internal alkenes were successfully employed, delivering *syn*-adducts with high diastereoselectivity. Mechanistically, *N*-aminopyridinium ylides participate in single-electron oxidation with a photoexcited catalyst to generate pyridinium radical cation **46-I**. This reactive intermediate undergoes 1,3-dipolar cycloaddition with an alkene, yielding cycloadduct **46-III**.

Scheme 17 *Ortho*-selective aminopyridylation of alkenes with *N*-aminopyridinium ylides.

Following deprotonation and *N*-*N* bond cleavage, a reductive SET event concludes the sequence, leading to *ortho*-selective aminopyridylation of alkenes.

Later, the same group reported a diastereoselective pyridyl lactamization enabled by a photo-mediated [3 + 2] cycloaddition with *N*-aminopyridinium ylides **49** as the bifunctional reagents, involving an intramolecular docking–migration process (Scheme 18a).<sup>22a</sup> This protocol exhibits high efficiency and exclusive *syn*-diastereoselectivity, providing direct access to *ortho*-pyridyl-substituted  $\gamma$ - and  $\delta$ -lactams in a single step. A proposed mechanism involves triplet–triplet energy transfer from a photocatalyst to an *N*-*N* pyridinium ylide species **49**. Upon irradiation, energy transfer from photoexcited *fac*-Ir(ppy)<sub>3</sub> to **49** populates the triplet state of the pyridinium ylide **49-I**. The resulting amidyl radical engages in intramolecular addition to a tethered alkene on the triplet potential energy surface, forming a C–N bond and generating a diradical intermediate **49-II**. Subsequent intersystem crossing and radical recombination at the *ortho*-position of the pyridinium ring lead to a dearomatized species **49-IV**, which upon proton transfer affords the final lactam product. The diastereoselectivity ratio (d.r.) is excellent primarily because the reaction proceeds *via* a stepwise, triplet diradical intermediate in a stereoconvergent manner. Regardless of the initial *E/Z* configuration of the alkene, the cyclization occurs through a favored conformation that minimizes steric repulsion between the substituents on the alkene and the lactam backbone.

In a related yet mechanistically distinct approach, Stephenson *et al.* developed a photocatalytic intramolecular aminoarylation of unactivated alkenes using *N*-acylsulfonamides **49'** as bifunctional reagents (Scheme 18b).<sup>22b</sup> This transformation proceeds *via* a nitrogen-centered radical generated

(a) Diastereoselective [3+2] cycloaddition of *N*-*N* pyridinium ylides with alkenes

(b) Intramolecular alkene aminoarylation enabled by desulfonylative aryl migration

Scheme 18 Radical docking–migration strategies for alkene aminoarylation.

through a sequential deprotonation and single-electron oxidation under photoredox conditions. The resulting sulfonamidyl radical undergoes 5-*exo-trig* cyclization onto a tethered alkene, followed by a desulfonylative 1,4-aryl migration to deliver lactam **50'**. The method tolerates a broad range of substrates, offering complementary access to structurally diverse, densely functionalized lactam frameworks under mild conditions without the need for transition-metal cross-coupling catalysts.

## 2.2 Asymmetric (hetero)aryl migration

In 2024, Nevado *et al.* reported a photocatalytic asymmetric aminoarylation of alkenes using chiral arylsulfonamide **51** as bifunctional reagents (Scheme 19).<sup>23</sup> This strategy leverages the

sulfinyl group as a traceless chiral auxiliary to install amino and aryl groups simultaneously across the  $\pi$ -system with exceptional regio- and stereo-control. The process initiates through single-electron oxidation of the electron-rich alkene or the deprotonated sulfinamide, depending on the substrate. The resulting nitrogen-centered radical **51-II** adds regioselectively to the terminal position of disubstituted alkenes to form a C–N bond. The subsequent radical-mediated 1,4-aryl migration *via* a Smiles rearrangement forges the C–C bond, delivering enantiomerically enriched  $\beta,\beta$ -diarylethylamines, aryl- $\alpha,\beta$ -ethylenediamines, or  $\alpha$ -aryl- $\beta$ -aminoalcohols. The sulfinyl group is cleaved *in situ* under the reaction conditions, rendering the chiral auxiliary traceless. The method exhibits broad functional group tolerance and high stereoselectivity, enabling the construction of two contiguous stereocenters in a single step. The *d.r.* is excellent because the reaction employs a chiral arylsulfinylamide reagent where the sulfinyl group acts as a traceless chiral auxiliary. This auxiliary controls the absolute stereochemistry during C–N bond formation. The subsequent 1,4-aryl migration proceeds through a stereospecific, conformationally restricted transition state, minimizing competing pathways. Additionally, the reaction is performed at low temperature, further enhancing stereocontrol. Mechanistic studies, including Stern–Volmer quenching experiments and DFT calculations, support a dual initiation pathway and

Scheme 20 Asymmetric radical aminoarylation of alkenes.

elucidate the origin of stereocontrol, which is governed by the chiral sulfoxide during the radical addition step.

Stephenson *et al.* reported a similar example of asymmetric radical aminoarylation of alkenes employing chiral aryl sulfinamides **54** as bifunctional reagents (Scheme 20).<sup>17</sup> The reaction of enantiopure (*S*)-**54** with vinylcyclohexane afforded the corresponding product (*S*)-**55** in 53% yield with 89 : 11 er. When the temperature was lowered to 0 °C, the product was obtained in an improved yield of 58% and with higher stereoselectivity (96 : 4 er). Meanwhile, the reaction of (*S*)-**54** with 4-bromobutene yielded the enantioenriched product **56**, which underwent subsequent cyclization to give pyrrolidine (*S*)-**57** in 86 : 14 er. However, the authors only investigated two examples, with a mechanism analogous to that in Scheme 13.

In 2024, our group disclosed the asymmetric amino(hetero)arylation of alkenes employing chiral sulfoximines **58** as bifunctional reagents (Scheme 21).<sup>24</sup> The bifunctional reagents were readily synthesized in three steps: asymmetric oxidation of the thioether to the sulfoxide, followed by further oxidation to the sulfoximine and subsequent chlorination. This sequence afforded the products in good yields and facilitated gram-scale production. This strategy enables the preparation of enantioenriched  $\beta$ -(hetero)arylethylamines without the need for transition-metal catalysts or additional photocatalysts. The method exhibits broad functional group tolerance, accommodating sensitive motifs such as boronic ester, aldehyde, and free alcohol, and proves applicable to the late-stage functionalization of complex molecules. Preliminary mechanistic studies, including radical trapping and cyclopropane ring-opening experiments, support a radical docking–migration pathway, while deuterium labelling confirms the role of the acetate base as the acetyl source in the final product. In the proposed mechanism, *R*-**58** undergoes homolytic cleavage of the N–Cl bond under visible-light irradiation, generating the *N*-centered radical intermediate **58-I**. This radical adds to styrene, forming an alkyl radical that subsequently undergoes intramolecular cyclization with the benzothiazolyl group to afford spiro intermediate **58-II**. Alternatively, radical **58-I** may participate in a hydrogen atom

Scheme 19 Asymmetric radical aminoarylation of alkenes using chiral arylsulfinamides as bifunctional reagents.

Scheme 21 Asymmetric radical aminoheterarylation of alkenes with chiral sulfoximine reagents.

transfer process to yield the N–H precursor, which can be recovered and reconverted into the sulfoximine reagent. The C–C bond formation occurs with *S*-configuration *via* the favored transition state **TS-I**; the **TS-II** is disfavored due to steric repulsion between the phenyl and ethyl groups. The ensuing heteroaryl migration is a stereospecific step that transfers the chirality from the sulfur center to the carbon backbone with high fidelity, concurrently establishing the new C–C bond and leading to sulfur-centered radical **58-III**. This radical then tautomerizes to sulfenamidyl radical **58-IV**, which abstracts a hydrogen atom from the solvent to give species **58-V**. Finally, **58-V** reacts with potassium acetate to deliver the desired product *S*-**60**.

### 2.3 Alkynyl migration

In 2019, our group disclosed a radical alkynylative functionalization of alkenes, achieving the concurrent incorporation of alkynyl and monofluoroalkyl groups (Scheme 22).<sup>25</sup> This method employs the sulfone-based bifunctional reagents **61** featuring a bromofluoroacetate moiety as the radical docking

site and an alkynyl as the migrating group. Under copper catalysis, the fluoroalkyl radical **61-I** adds to the alkene, followed by an intramolecular migration of the alkynyl group *via* C–S bond cleavage and SO<sub>2</sub> extrusion. The resulting radical intermediate **61-IV** is subsequently terminated by a halogen atom abstracted from the solvent, completing a radical chain process. The reaction accommodates a broad range of alkene substrates, including both activated and unactivated alkenes. The *d.r.* is poor mainly because of the high reaction temperature and the terminating chlorine abstraction step proceeds without effective stereocontrol. This method provides efficient access to valuable monofluoroalkyl-substituted aliphatic alkynes, and exhibits considerable utility in the late-stage modification of complex molecules.

### 2.4 Oximino migration

In 2020, our group demonstrated the versatility of the polarity umpolung strategy enabled by the docking–migration process, and extended the migration group from the heteroaryl to the oximino moiety (Scheme 23).<sup>8</sup> Using the oximino-containing bifunctional sulfone reagents **64**, the radical oximino-alkylation of both activated and unactivated alkenes was achieved under photoredox conditions. The addition of LiCl as a Lewis acid additive was found to significantly enhance the reaction efficiency, likely through activation of the oximino group. This transformation proceeded *via* a mechanism

Scheme 22 Radical monofluoroalkylative alkylation of alkenes.

Scheme 23 Polarity-umpolung oximino-alkylation of alkenes.

analogous to that of the heteroaryl migration shown in Scheme 4, involving radical addition to the alkene, intramolecular oximino migration, and SO<sub>2</sub> extrusion, followed by reduction to yield the corresponding products.

## 2.5 Alkenyl migration

In 2021, our group applied the radical docking–migration strategy to concomitant installation of two unsaturated C–C bonds across alkenes (Scheme 24).<sup>26</sup> The devised bifunctional sulfone reagents **67** bear a bromoallenyl group and an alkenyl

Scheme 24 Radical 1,2-alkynylalkenylation and 1,2-enynylalkenylation of alkenes.

migrating group. Under mild photocatalytic conditions, single-electron reduction of the reagent generates a sulfone-stabilized allenyl radical **67-I**, which is sufficiently persistent to undergo intermolecular addition to alkenes to form the alkyl radical **67-II**. This radical docking event is followed by an intramolecular alkenyl migration and SO<sub>2</sub> extrusion cascade, delivering valuable 1,5-enyne products with exclusive stereoselectivity. The protocol exhibits broad substrate scope, encompassing styrenes, aliphatic alkenes, internal alkenes, and complex alkene molecules. By simply modulating the reaction solvent, the reaction was further extended to achieve 1,2-enynylalkenylation, providing direct access to densely functionalized enynes.

The radical fluoroalkylative alkenylation of alkenes was also accomplished by using the docking–migration strategy (Scheme 25).<sup>27</sup> This approach employed the bifunctional sulfone reagents **70** that contain both a bromofluoroalkyl group and an alkenyl migrating group, affording vinylated products exclusively as the *E*-isomer. Under mild photoredox catalysis with *fac*-Ir(ppy)<sub>3</sub>, the reaction is initiated *via* single-electron reduction of the C–Br bond, generating a fluoroalkyl radical **70-I**. This radical adds to alkene, and the resulting carbon-centered radical **70-II** undergoes an intramolecular cyclization with the tethered alkenyl sulfone moiety. This event triggers a sequence of alkenyl migration and SO<sub>2</sub> extrusion, leading to the formation of the final product. The *d.r.* is generally low because the terminating bromine abstraction step proceeds without effective stereocontrol. The transformation accommodates a wide array of

Scheme 25 Radical fluoroalkylative alkenylation of alkenes.

styrenes and aliphatic alkenes, as well as complex natural products and drug derivatives.

While the use of sulfone-based reagents enables remarkable transformations of both activated and unactivated alkenes, the extrusion of SO<sub>2</sub> limits the atom economy of the reaction. Moreover, current asymmetric strategies predominantly rely on chiral sulfur auxiliaries (sulfoximines, sulfinamides), which are excellent for stereocontrol but require additional synthetic steps to install. A general, catalytic enantioselective platform using chiral catalysts remains unexplored.

### 3 Alkyne difunctionalization

#### 3.1 (Hetero)Aryl migration

In 2024, our group reported the radical difunctionalization of unactivated aliphatic alkynes, achieving excellent chemo- and stereo-selectivity that have long remained elusive (Scheme 26).<sup>28</sup> The photoredox-neutral cascade enables the concomitant incorporation of a hydroxyalkyl and a (hetero)aryl group across the alkyne, providing modular access to a diverse array of highly functionalized *E*-allylic alcohols 75. This method is noteworthy for its remarkable tolerance of aliphatic alkynes containing benzylic C–H bonds prone to intramolecular hydrogen atom transfer, a common side reaction that compromises selectivity in such transformations. The protocol exhibits broad functional group compatibility, encompassing a wide range of sensitive structural motifs, and its utility is highlighted by successful applications in the late-stage modification of complex natural products and pharmaceutical molecules.

The proposed mechanism is depicted in Scheme 27. Initially, single-electron transfer from photoexcited *fac*-Ir(ppy)<sub>3</sub> to substrate 73 generates an alkyl radical intermediate 73-I, which

Scheme 26 *E*-Selective radical difunctionalization of unactivated alkynes.

Scheme 27 Proposed mechanism for radical difunctionalization of aliphatic alkynes.

undergoes addition to alkyne 74, yielding an alkenyl radical species 73-II. Cyclic voltammetry measurements of 73 confirmed that its C–Br bond is susceptible to reduction by the excited Ir<sup>III</sup>\* complex. Subsequent intramolecular capture of the alkenyl radical by the heteroaryl group initiates the migration of the functional group. DFT calculations indicate that the competing 1,5-HAT pathway is energetically less favourable, consistent with the absence of such products under the reaction conditions. The 1,4-aryl migration occurs *via* a lower energy transition state compared to 1,5-HAT, leading to the more

Scheme 28 Radical alkylarylation of alkynes using arylsulfonyl acetates as bifunctional reagents.

Scheme 29 Radical alkylarylation of alkynes using bis-sulfone bifunctional reagents.

stable intermediate **73-IV**. Extrusion of  $\text{SO}_2$  then affords radical species **73-V**. This radical is then oxidized by the *in situ* generated  $\text{Ir}^{\text{IV}}$  species, which regenerates the ground-state  $\text{Ir}^{\text{III}}$  catalyst and forms cationic intermediate **73-VI**. Nucleophilic addition of water to **73-VI** gives rise to intermediate **Z-75**. Finally, in the presence of the photosensitizer, energy transfer facilitates isomerization of **Z-75** to the thermodynamically stable product **E-75**.

In 2024, Liu *et al.* achieved the radical difunctionalization of internal alkynes by employing arylsulfonyl acetates **76** as bifunctional reagents (Scheme 28).<sup>29</sup> Under photoredox catalysis, single-electron oxidation of the sulfonyl acetate reagent generates an electrophilic carbon-centered radical **76-I**, which regioselectively adds to the alkyne, forming a vinyl radical intermediate **76-II**. This species then undergoes intramolecular *ipso*-addition to the tethered (hetero)arene, triggering a sequential Smiles rearrangement with concomitant extrusion of  $\text{SO}_2$ , which facilitates aryl migration and forges a new C–C bond. This cascade successfully installs both an alkyl carboxylate and an aryl group across the alkyne in a single operation, affording valuable all-carbon tetrasubstituted alkenes. The method exhibits broad substrate scope, excellent functional group tolerance, and applicability to both internal and terminal alkynes.

Subsequently, Liu *et al.* employed bis-sulfones **79** as bifunctional reagents in alkyne difunctionalization (Scheme 29).<sup>30</sup> The reaction accommodates a range of substituted bis-sulfones and unsaturated substrates, including internal alkenes and alkynes, affording structurally diverse tetrasubstituted alkenes. However, the reaction proceeds without

Scheme 30 Photocatalytic Conia-ene reaction/Smiles rearrangement cascade.

stereocontrol, leading to the formation of multi-substituted alkenes as *Z/E* mixtures. Mechanistic investigations, supported by cyclic voltammetry and Stern–Volmer quenching studies, indicate that the process begins with deprotonation of the bis-sulfone **79** to form an anionic intermediate. This species undergoes single-electron oxidation by the photoexcited 4CzIPN catalyst to generate an alkyl radical **79-I**. Subsequent addition of **79-I** across the alkyne produces radical intermediate **79-II**, which engages in an intramolecular *ipso*-cyclization to form spirocyclic species **79-III**. Fragmentation of **79-III** with concomitant  $\text{SO}_2$  extrusion yields a new alkyl radical **79-IV**, which is then reduced and protonated to furnish the final product while regenerating the ground-state photocatalyst.

Later, Liu *et al.* demonstrated an extension to intramolecular alkyne cyclization, employing alkyne-tethered  $\alpha$ -sulfonyl esters **82** as substrates (Scheme 30).<sup>31</sup> Under photoredox catalysis, single-electron oxidation generates a carbon-centered radical **82-I**, which undergoes regioselective *5-exo-dig* cyclization onto the alkyne, forming a vinyl radical intermediate **82-II**. This species triggers an intramolecular Smiles rearrangement, facilitating aryl migration from the sulfonyl to the vinyl carbon with simultaneous extrusion of  $\text{SO}_2$ , thereby forging a new C–C bond. This cascade effectively bypasses the traditional 1,5-hydrogen shift of classical Conia-ene reaction, enabling the direct synthesis of cyclic tetrasubstituted alkenes. The method exhibits broad substrate scope, good functional group tolerance, and is applicable to the construction of both five- and six-membered carbocycles as well as lactone-fused systems. The utility of this method is highlighted by its ability to efficiently

Scheme 31 Radical carbamoylation of alkynes with *N*-aryl oxamic acids.

cyclize low-reactivity substrates that are recalcitrant to conventional Conia-ene conditions.

Kuninobu *et al.* demonstrated the utility of *N*-aryl oxamic acids **84** as bifunctional reagents for the radical carbamoylation of terminal alkynes under visible-light irradiation (Scheme 31).<sup>32</sup> This approach generates a carbamoyl radical *via* decarboxylation, which

then adds to alkynes. The resulting vinyl radical intermediate undergoes a radical-mediated 1,4-aryl migration *via* cleavage of the C–N bond, simultaneously forging a new C–C bond and delivering valuable  $\beta,\beta$ -diarylacrylamide products in moderate to good yields. The reaction exhibits a broad substrate scope, accommodating various *N*-aryl oxamic acids and arylacetylenes bearing both electron-donating and withdrawing groups.

Our group disclosed a *Z*-selective radical arylheteroarylation of aromatic alkynes using tertiary alcohol-substituted aryldiazonium salts **87** as bifunctional reagents (Scheme 32).<sup>33</sup> This process employs cuprous chloride to reduce the diazonium salt, generating an aryl radical **87-I** that adds to the alkyne. The resulting vinyl radical **87-II** undergoes intramolecular cyclization followed by a 1,5-heteroaryl migration *via*  $\beta$ -scission of a C–C bond, leading to the formation of triarylethylenes with exceptional *Z*-selectivity. The method is applicable to a wide range of aromatic and heteroaromatic alkynes, including complex drug derivatives. The reaction proceeds efficiently on a gram scale and the products serve as versatile intermediates for further transformations, including the synthesis of a novel spin-trapping reagent capable of detecting methyl radicals.

### 3.2 Imino migration

Liu *et al.* reported the use of oxime esters **90** as bifunctional reagents for the radical alkylation of alkynes under photoredox conditions (Scheme 33).<sup>34</sup> This reaction proceeds *via*

Scheme 32 *Z*-Selective radical arylheteroarylation of alkynes.

Scheme 33 Oxime esters as bifunctional reagents for radical alkylation of alkynes.

a sequence involving single-electron oxidation of the reagent, generating a carbon-centered radical **90-I** that adds across the alkyne. The resulting vinyl radical **90-II** undergoes 6-*exo-trig* cyclization, followed by  $\beta$ -scission of the N–O bond and decarboxylation, leading to migration of the imino group and formation of tetrasubstituted alkenes. However, the stereoselectivity of the alkene products is not satisfactory. The method is amenable to gram-scale synthesis. Additionally, the products serve as versatile intermediates for further transformations, including hydrolysis to ketones and cyclization to poly-substituted pyrroles.

Achieving high stereoselectivity in alkyne difunctionalization, as exemplified here, is a landmark achievement. However, a pervasive challenge across many radical alkyne reactions is the control of *Z/E* selectivity. While docking-migration can enforce specific geometries, many systems still yield mixtures.

## 4 Miscellaneous

### 4.1 Difunctionalization of enamine intermediates

Our group disclosed a radical-mediated  $\alpha$ -*tert*-alkylation of aliphatic aldehydes *via* consecutive 1,4- and 1,3-heteroaryl migrations, providing an efficient route to structurally complex aliphatic aldehydes under metal-free photochemical conditions

Scheme 34 Radical-mediated  $\alpha$ -*tert*-alkylation of aldehydes *via* consecutive heteroaryl migrations.

(Scheme 34).<sup>35</sup> The reaction is initiated by the formation of an electron donor–acceptor (EDA) complex between an *in situ*-generated enamine intermediate and an  $\alpha$ -bromo sulfone, which upon photoexcitation generates a radical species. This intermediate undergoes a sequence of 1,4- and 1,3-heteroaryl migrations, ultimately leading to the installation of a tertiary alkyl group at the  $\alpha$ -position of the aldehyde. Mechanistic studies, including radical trapping experiments, crossover tests, and DFT calculations, support a radical chain process involving intramolecular migration steps. Mechanistic investigations delineate the following sequence: initially, condensation of the aldehyde **94** with a secondary amine generates an enamine **93-I**, which associates with the  $\alpha$ -bromo sulfone reagent **93** to form an electron donor–acceptor complex. Photoexcitation of this assembly triggers a single-electron transfer, furnishing an  $\alpha$ -sulfonyl alkyl radical **93-II** and an enamine-derived radical cation. The electrophilic carbon-centered radical is then captured by the nucleophilic enamine, forming a new C–C bond and generating the radical species **93-III**. This radical adduct subsequently extrudes  $SO_2$  *via* a 1,4-group migration. The resulting alkyl radical **93-IV** then undergoes a less common 1,3-heteroaryl shift, proposed to proceed *via* a constrained four-membered ring transition state, to deliver a stabilized  $\alpha$ -amino radical **93-VI**. Finally, this intermediate is oxidized by the  $\alpha$ -bromo sulfone **93**, regenerating the initial radical species **93-II** to propagate the chain and yielding an iminium ion **93-VII**, which upon hydrolysis furnishes the observed  $\alpha$ -tertiary aldehyde product.

Scheme 35 *cis*-Difluoromethyl heteroarylative dearomatization.

## 4.2 Difunctionalization of heteroarenes and polycyclic aromatic hydrocarbons

Recently, our group also achieved an uncyclized *cis*-selective difluoromethyl hetarylation of heteroarenes under mild photochemical conditions without an external photocatalyst (Scheme 35).<sup>36</sup> This method utilizes bifunctional sulfone reagents **96** to concomitantly install CF<sub>2</sub>H and hetaryl groups across the C=C bonds of indoles, benzothiophenes, furans, thiophenes, and a few polycyclic aromatic hydrocarbons. The transformation proceeds under blue light irradiation in a DME/H<sub>2</sub>O solvent using sodium ascorbate as the reductant. The mechanism is proposed to initiate *via* single-electron transfer between the sulfone reagent and sodium ascorbate, generating an electrophilic difluoroalkyl radical **96-I**. This radical adds to the heteroarene, forming an adduct that undergoes an intramolecular heteroaryl migration through a kinetically favored five-membered cyclic transition state. Subsequent extrusion of SO<sub>2</sub> delivers a difluoromethyl radical **96-IV**, which abstracts a hydrogen atom from the solvent to furnish the final *cis*-product. The newly formed radical **96-V** abstracts Br atom from the sulfone reagent, regenerating intermediate **96-I** to propagate the radical chain. This method features broad substrate scope, excellent functional group tolerance, and high stereoselectivity, providing direct access to thermodynamically disfavored *cis*-difunctionalized (hetero)aryl derivatives.

## 5 Summary and outlook

The radical docking–migration strategy has established itself as a powerful and versatile platform for the difunctionalization of alkenes and alkynes, enabling the concomitant incorporation of two distinct functional groups across unsaturated carbon–carbon bonds with high levels of regio- and stereoselectivity. By employing rationally designed bifunctional reagents derived from sulfones, tertiary alcohols, diaryl ethers, sulfinamides, and sulfoximines, this approach proves applicable to both activated and unactivated alkenes and alkynes. The modular nature of these reagents permits the introduction of diverse migrating groups—such as aryl, heteroaryl, alkynyl, oximino, alkenyl, and imino moieties—thereby facilitating efficient access to a broad spectrum of complex molecular architecture from simple starting materials.

Notably, asymmetric versions of these transformations have been realized through the use of chiral sulfoximines and sulfinamides as bifunctional reagents, enabling the construction of enantioenriched scaffolds. Mechanistic investigations have shed light on key steps, including radical addition, migration, and termination, often corroborated by DFT calculations and spectroscopic evidence, thereby affirming the robustness of this strategy.

### 5.1 Design principles of bifunctional reagents

The use of sulfonyl as the linker in radical-mediated Smiles rearrangements offers unique advantages. The first advantage lies in the exergonic driving force provided by the extrusion of gaseous SO<sub>2</sub>, which propels the migration process. Concurrently, the sulfonyl group enables kinetically favored 5-membered cyclic transition states for the intramolecular

migration and inverts the polarity of the initial radical, making it electrophilic and thus compatible with unactivated alkenes. Furthermore, sulfonyl acts as a traceless linker, exiting cleanly as a gas and leaving no residue in the product. In addition, when employed as linkers, both chiral aryl sulfinamides and chiral sulfoximines utilize their stereogenic sulfur (IV or VI) center as a temporary chiral auxiliary. During the radical Smiles rearrangement, chiral information is transferred from this sulfur atom to a new carbon stereocenter in the product, typically with high stereospecificity.

### 5.2 Synthetic accessibility of bifunctional reagents

Although most of the bifunctional reagents described herein are not commercially available, their synthetic routes have been systematically optimized, allowing most to be efficiently prepared in 2–4 steps from readily available starting materials. Although the synthetic efforts to access bifunctional reagents is a disadvantageous factor, this is offset by the high-value, complex products obtained in a single operation.

### 5.3 Reasons for the choice of the catalytic system

The choice of catalytic system is dictated by the electronic properties of the bifunctional reagents and the desired reaction pathways. Photoredox catalysis is predominantly employed to generate radical species from C–Br and C–I bonds under mild conditions *via* SET. Copper catalysis is often selected to mediate halogen atom transfer (XAT) or SET processes, particularly when involving diazonium salts or facilitating radical chain propagations. EDA complex photoactivation provides a metal- and external photocatalyst-free pathway, ideal for generating radicals from reagents with matched redox potentials. Finally, catalyst-free conditions are viable when the reagent itself (*e.g.*, diazonium salts) can serve as a radical precursor upon photoexcitation.

### 5.4 Outlook

Despite rapid progress in this area, several challenges and opportunities remain. First, the development of non-sulfone-based linkers is highly desirable to broaden reagent diversity and enhance functional group compatibility. Second, although asymmetric variants have been achieved using chiral sulfur auxiliaries, general catalytic enantioselective protocols—particularly those employing chiral photocatalysts or Lewis acids—remain underdeveloped. Third, asymmetric migration of other valuable groups, such as cyano, ester, and phosphorus-based functionalities, remains largely unexplored and constitutes a promising direction for future research. Finally, the application of this methodology to the synthesis of complex functional molecules—including natural products, pharmaceuticals, and polymeric materials—represents an important and anticipated future endeavour.
