Accelerated charge transfer via a nickel tungstate modulated cadmium sulfide p–n heterojunction for photocatalytic hydrogen evolution

Yongke Zhang^{abc} and Zhiliang Jin  ^{*abc}

Improving the efficiency of charge separation is an important aspect in photocatalysis. With NiWO₄ modulation, the results of the Mott–Schottky test, short fluorescence lifetime (1.87 ns), faster electron transfer rate constant ($K_{ET} = 2.82 \times 10^8 \text{ s}^{-1}$), larger efficiency of electron injection ($\eta_{inj} = 52.7\%$), high photocurrent response, smaller transfer resistance ($R_{film} = 2785 \Omega \text{ cm}^2$) and reaction resistance ($R_{ct} = 1.74 \Omega \text{ cm}^2$) showed that a new interface electric field was established and a more effective thermodynamic charge transfer path was formed. This evidence greatly supported the fact that the separation and transfer of space charges over CdS p–n were accelerated via NiWO₄ modulation. The [CdS/NiWO₄ (30%)] sample had the best H₂ production performance, namely, the maximum H₂ production in 5 hours was 757 μmol , which was 7.35 times higher than that of pure CdS nanorods. Moreover, a series of characterization results also showed that the NiWO₄ decorated CdS p–n heterojunction improved the efficiency of photo-generated charge separation and the SEM, XRD, TEM, EDX, XPS, UV-vis DRS, transient fluorescence, electro-chemistry etc. results were in good agreement with each other.

1. Introduction

The continuous depletion of fossil energy has caused mankind to face two major problems: energy shortage and environmental pollution.^{1–3} These two issues have posed tremendous threats to the survival and development of human beings. Solar energy is a kind of sustainable clean energy.⁴ Therefore, how to make good use of solar energy and improve the efficiency of energy conversion are the key to solving the energy crisis and environmental pollution problems. At present, photocatalytic technology is considered as an effective countermeasure, which can continuously convert low-density solar energy into chemical energy through photochemical reactions and has the advantages of low cost and environmental friendliness. It exhibits a very wide range of applications, such as in dye-sensitized solar cells,⁵ photocatalytic degradation of pollutants,⁶ photocatalytic cleavage of water to H₂,⁷ photoelectrochemical cathodic protection⁸ and photocatalytic reduction of CO₂.^{9,10}

In 1972, Fujishima and Honda discovered that TiO₂ can decompose water into H₂ and O₂ under ultraviolet light,¹¹ and since then a large number of scientists have focused their attention on semiconductor photocatalysts such as ZnO,¹² CdS,^{13,14} BiVO₄,^{15,16} and Ag₃PO₄.¹⁷ In addition to having an appropriate band gap energy level, an ideal semiconductor should have low cost, readily available materials, high stability, and be non-toxic, as well as exhibit efficient use of solar energy. However, few materials can satisfy the above conditions at the same time. For example, GaAs,¹⁸ PbS,¹⁹ and CdS are toxic, and they are prone to photo-corrosion and poor stability in aqueous solutions. ZnO is unstable in aqueous solution because it easily dissolves in water and can form Zn(OH)₂ on the surface of ZnO, thereby passivating the photocatalyst. The conduction band (CB) of Fe₂O₃,²⁰ SnO₂ (ref. 21) and WO₃ (ref. 22 and 23) is located in the lower part of the reversible hydrogen potential, which means that these materials need to be subjected to external bias to complete the hydrolysis reaction. However, photocatalytic technology faces many problems in practical applications, for example, how to increase the light absorption range of the photoelectric conversion material, the separation ability of the photoelectron–hole, and the stability of the photocatalytic catalytic performance.²⁴ Through extensive research, scientists have found that constructing an interface heterojunction system is an effective method to improve the separation efficiency of photogenerated electrons and holes.²⁵ The existence of these

electric fields can increase the efficiency of separation of photogenerated electrons and holes and improve the photocatalytic properties.²⁶

CdS has become a research hotspot in the field of photocatalysis in recent years due to its characteristics of visible light response and high cost performance. It has also become a hotspot in the field of photoelectrocatalysis. It is the ideal bandgap of CdS and the suitable conduction band (CB) position that satisfy the thermodynamic and kinetic requirements of photocatalytic water splitting.²⁷ However, the lifetime of carriers generated by CdS itself is short and the redox reaction cannot be completed well. When the photogenerated holes are generated on the surface of CdS, if they cannot react with the surrounding sacrificial reagents or rapidly transfer to other substances, they will quickly oxidize CdS, resulting in rapid photo-corrosion²⁸ and rapid crystal structure collapse. The photocatalytic performance also deteriorates.

Therefore, in order to improve the stability and photocatalytic performance of the CdS photocatalyst, many researchers have extensively applied various nano-morphologies of CdS semiconductor-based materials to the field of photocatalysis: (1) CdS hollow spheres: Zhang J. L. and Xing M. Y. *et al.* reported the $\text{MnO}_x/\text{CdS}/\text{CoP}$ hollow sphere photocatalyst, which was loaded with two cocatalysts (inside MnO_x and outside CoP) for enhancing photocatalytic H_2 evolution activities.²⁹ Han J. and Wang M. G. *et al.* prepared CdS/TiO_2 hollow sphere heterojunction photocatalysts to improve the photocatalytic activity.³⁰ (2) CdS nanorods: Li Z. Y. and Liang Q. *et al.* synthesized highly stable $\text{CdS}/\text{UIO-66-NH}_2$ core-shell nanorods for enhancing photocatalytic activity.³¹ Zeng R. C. and Feng C. *et al.* prepared MoS_2 cluster modified CdS nanorods through a one-pot solvothermal method at lower temperature.³² (3) CdS nanowires: Yu J. G. and Zhang J. Y. *et al.* prepared a $\text{CdS}/\text{g-C}_3\text{N}_4$ core/shell nanowire hybrid system by solvothermal and chemisorption methods.²⁸ (4) CdS quantum dots: Shi J. W. and Zou Y. J. *et al.* reported the study on CdS QD decorated WS_2/CN 2D/2D nanosheets for water splitting.³³ Wang X. C. and Zheng D. D. reported the integration of CdS quantum dots on hollow graphitic carbon nitride nanospheres for hydrogen evolution.³⁴ (5) CdS nanoparticles: Fang P. F. and Wang H. M. *et al.* reported the study on WO_3/WS_2 nanorods coupled with CdS nanoparticles for hydrogen evolution.³⁵ There are also some researchers who constructed a p-n type heterojunction³⁶ by forming a built-in electric field from the n-type semiconductor to the p-type CdS between the two semiconductors, thereby accelerating the separation of electrons and holes and effectively suppressing the recombination of the charges.

NiWO_4 has a characteristic wolframite structure with a monoclinic unit cell and space group,³⁷ suitable band gap energy (2.20 eV),³⁸ sufficient chemical and thermal stability, good quantum size effect, and excellent catalytic performance.³⁹ It is these properties that have attracted extensive attention and research in the field of photocatalysis, making it an ideal catalyst for photocatalytic decomposition of water to produce H_2 . However, there are few reports on the use of

the NiWO_4 photocatalyst for H_2 production from water splitting.

In this paper, we succeeded in constructing an efficient photocatalytic H_2 production system of CdS/NiWO_4 . The first step is to synthesize CdS nanorods, and then load NiWO_4 to the surface of the CdS nanorods through a simple hydrothermal reaction. In the meantime, the p-n junction is formed between the p-type NiWO_4 (ref. 40) and n-type CdS, which accelerates the transfer of electrons and holes. As a result, the photocatalytic H_2 production rate is greatly improved.

2. Experimental section

2.1 Photocatalyst preparation

2.1.1 Preparation of CdS nanorods. A certain amount of $\text{Cd}(\text{NO}_3)_2 \cdot 6\text{H}_2\text{O}$ and NH_2CSNH_2 are dissolved in 50 ml of ethylenediamine, and magnetically stirred for 30 minutes. Subsequently, the solution is transferred to an 80 ml polytetrafluoroethylene autoclave and heated to 160 °C for 48 h. After the reaction is completed and cooled to room temperature, the sample is obtained by centrifugation. Then, the precipitate is washed with distilled water and ethanol three times and dried at 60 °C for 10 hours.

2.1.2 Preparation of CdS/NiWO_4 photocatalysts. CdS/NiWO_4 with different contents of NiWO_4 [$\text{m}(\text{NiWO}_4)/\text{m}(\text{CdS}) \times 100\% = 5, 10, 30, 50$ and 70] are prepared by a solvothermal method. Taking the preparation of the [CdS/NiWO_4 (50%)] catalyst as an example, in a typical synthesis of the composite catalysts, firstly, 200 mg of the above-prepared CdS nanorods are added to a 100 ml beaker containing 60 ml of DI water and sonicated for 20 minutes. Soon afterwards, 77.46 mg of $\text{NiCl}_2 \cdot 6\text{H}_2\text{O}$ and 107.5 mg $\text{Na}_2\text{WO}_4 \cdot 6\text{H}_2\text{O}$ are added to the above solution. After magnetic stirring for 30 minutes, the above solution is transferred to a 100 mL autoclave and heated to 130 °C for 12 h. Finally, after cooling down to room temperature, the sample is obtained by centrifugation, washing and drying. The other catalysts with different percentages NiWO_4 are also prepared in the same way. We use [CdS/NiWO_4 (x%)] ($x = 5, 10, 30, 50, 70$) to represent these samples.

2.2 Photocatalytic H_2 measurements

We use 62 ml reaction bottles and a PCX50A Discover (Perfectlight, Beijing) for photocatalytic H_2 production measurements. The specific steps are as follows: first of all, 20 mg of the sample, 30 ml of 10 vol% lactic acid and a magnetic stir bar are added to the reaction bottle. Then, after stirring for 5 minutes, we put the reaction bottle into the ultrasonic cleaner for sonication for 10 minutes. Subsequently, the system is ventilated with N_2 for about 30 min to remove O_2 . Ultimately, we place the reactor on the multi-channel reaction system and extract 0.5 ml of gas to analyze through gas chromatography (Tianmei GC7900, TCD, 13× column, N_2 as the carrier). We use the external standard method to calculate the amount of H_2 produced.

Next, we test the apparent quantum efficiency (AQE) of the [CdS/NiWO_4 (30%)] composite catalyst. The specific steps

are as follows: 20 mg of the [CdS/NiWO₄ (30%)] catalyst is placed in a 62 ml quartz reaction flask containing 30 ml of 10% lactic acid solution, then the oxygen in the bottle is replaced with N₂ for 10 minutes and ultrasonic treatment is conducted for 10 minutes. A 300 W Xe lamp light source (CEL-HXF300) with 400, 420, 450, 475, 500, 520, 550 and 600 nm band pass filters is used as the light source to irradiate the reaction solution for 1 h separately. A PL-MW200 photoradiometer (Perfect Light) is used to measure the photon flux of the incident light. Based on eqn (1), the AQE at different wavelengths is calculated.

$$\text{AQE} = \frac{2 \times \text{the number of evolved hydrogen molecules}}{\text{the number of incident photons}} \times 100\% \quad (1)$$

2.3 Photoelectrochemical measurements

Photoelectrochemistry experiments are conducted on an electrochemical workstation (VersaSTAT4-400, AMETEK) using a homemade standard three-electrode cell, whose reference electrode, counter electrode and working electrode are respectively a saturated calomel electrode (SCE), Pt electrode and FTO (1 × 2 cm²) drop-coating homogeneous catalyst. The electrolyte is a Na₂SO₄ aqueous solution (0.2 mol L⁻¹). A 300 W xenon lamp with a cut-off filter of 420 nm is used as the light source. The Mott-Schottky plot is recorded at 5 kHz frequency in the dark. The potential ranges from -1.5 to 2.0 V (vs. SCE).

2.4 Characterization

The crystalline structure, element composition and UV-vis diffuse reflectance spectra are respectively measured using an X-ray diffractometer (XRD, Rigaku RINT-2000), X-ray photoelectron spectroscope (XPS, ESCALAB 250Xi) and UV-2550 (Shimadzu) spectrometer (BaSO₄ as the reference). The images of sample morphology are obtained using a field-emission scanning electron microscope (FESEM, JSM-6701F)

and a transmission electron microscope (TEM, Tecnai G2-TF30). The nitrogen adsorption-desorption isotherms are measured at 77 K with an ASAP 2020 M instrument and analyzed using the Brunauer-Emmett-Teller (BET) equation. The pore size distribution plots are obtained by the Barrett-Joyner-Halenda (BJH) model. The photoluminescence (PL) emission spectra and time-resolved PL (TRPL) spectra are detected using a FluoroMAX-4 spectrometer (Horiba, France).

3. Results and discussion

3.1 XRD, SEM, and TEM analysis

3.1.1 XRD analysis. Fig. 1 shows the XRD patterns of the samples. In Fig. 1(A), in order to more intuitively observe and analyze the phase and crystallinity of the samples, we select the [CdS/NiWO₄ (70%)] sample for analysis. It can be seen that in the characteristic peaks of the [CdS/NiWO₄ (70%)] sample, not only the characteristic peaks of CdS but also the characteristic peaks of NiWO₄ can be indexed. Through further observation, it can be observed that there are seven main sharp peaks at 2θ = 24.85, 26.48, 28.24, 36.58, 43.78, 47.77 and 51.88°, matching well with the corresponding lattice faces of (100), (330), (101), (102), (110), (103) and (112), respectively (CdS with a space group of *P63mc* (no. 186), JCPDS no. 65-3414),^{42,43} and that there are four peaks located at 19.29, 31.11, 36.58 and 54.60°, which are consistent with the monoclinic NiWO₄ phase (JCPDS no. 15-0755) with a space group of *P2/c* (no. 13) and correspond to the (100), (-111), (002) and (-202) planes, respectively. The three strong peaks of CdS and NiWO₄ are obvious, and there are basically no other impurity peaks. Fig. 1(B) shows the XRD patterns of [CdS/NiWO₄ (x%)] (x = 5, 10, 30, 50, 70). When the content of NiWO₄ is gradually increased, the intensity of the characteristic peak of NiWO₄ in the XRD pattern is also gradually enhanced, especially that of the 31.11° characteristic peak, demonstrating that the content of NiWO₄ loaded on the CdS/NiWO₄ is also gradually increasing.

Fig. 1 The XRD patterns of (A) CdS/NiWO₄ (70%) and JCPDS of CdS and NiWO₄; (B) the XRD patterns of [CdS/NiWO₄ (x%)] (x = 5, 10, 30, 50, 70).

3.1.2 SEM analysis. The morphology of CdS nanorods and [CdS/NiWO₄ (30%)] is examined by SEM, the results of which are utilized to offer more intuitive information about the space shape, size, sample distribution of samples and so on. Fig. 2(A) and (B) show the SEM photographs of CdS nanorods at low magnification and high magnification, respectively. It can be clearly seen that the CdS nanorods are uniformly dispersed, with a size distribution of approximately 1 μm and a relatively smooth surface. Fig. 2(C) and (D) show the SEM images of [CdS/NiWO₄ (30%)] at low magnification and high magnification, respectively. It can be found that the comparatively smooth surface of CdS nanorods becomes rough, and that there are many plate-like structures adhering to the surface of the CdS nanorods, manifesting that NiWO₄ successfully attached to the surface of CdS nanorods, which can be verified by further TEM characterization.

3.1.3 TEM analysis. TEM and HRTEM characterizations of the samples are of great importance in increasing the understanding of the internal structure and the morphology after the loading of NiWO₄. In Fig. 3(A), we can further see that the CdS nanorods are uniformly dispersed, and the surface is relatively smooth, which is consistent with the XRD and the SEM results. On further observation of the HRTEM image in Fig. 3(B), the lattice spacing in the middle of two adjacent lattice planes is about 0.336 nm,²⁷ which matches with the (002) lattice plane of CdS. Fig. 3(C and D) show the TEM images of [CdS/NiWO₄ (30%)] at different magnifications from

low to high. It is very clear that there is a sheet-like structure attached to the surface of the CdS nanorod. This is in agreement with the SEM image in Fig. 2(D). Further analysis of the HRTEM image in Fig. 3(E) shows that the lattice spacings in the middle of two adjacent lattice planes are about 0.336 and 0.245 nm,²⁹ which matched the (002) lattice plane of CdS (ref. 27) and the (002) lattice plane of the monoclinic NiWO₄,⁴³ respectively. Fig. 3(F) shows the energy dispersive X-ray spectroscopy (EDX) spectrum of [CdS/NiWO₄ (30%)] and the results demonstrate the presence of S, Cd, Ni, W and O elements.

3.2 XPS, BET, and UV-vis DRS analysis

3.2.1 XPS analysis. In order to further understand the element composition of the sample and the valence of each element, XPS studies on as-prepared [CdS/NiWO₄ (30%)] are carried out so that we can obtain deeper insights. From the survey spectrum (Fig. 4(A)), we can find that the composite catalyst mainly consists of S, Cd, Ni, W and O elements. It can be seen that the S 2p spectrum (Fig. 4(B)) can be deconvoluted into two peaks including 161.76 eV for S 2p_{3/2} and 162.94 eV for S 2p_{1/2},⁴⁴ and that the Cd 3d spectrum (Fig. 4(C)) can be resolved into two peaks located at 412.05 and 405.26 eV, which are ascribed to Cd 3d_{5/2} and Cd 3d_{3/2}, respectively.⁴⁵ In the Ni 2p spectrum in Fig. 4(D), it can be seen that there are six distinct characteristic peaks in the Ni

Fig. 2 SEM images: (A and B) CdS nanorods; (C and D) CdS/NiWO₄ (30%).

Fig. 3 (A and B) TEM and HRTEM images of CdS nanorods, (C–E) TEM and HRTEM images of [CdS/NiWO₄ (30%)] and (F) EDX spectrum of [CdS/NiWO₄ (30%)].

spectrum, which belong to the Ni 2p_{3/2} and Ni 2p_{1/2} area, respectively. Further observation of the Ni 2p spectrum reveals that there are three distinct characteristic binding energy peaks located in the Ni 2p_{3/2} region. The three peaks are located at 852.3, 855.9 and 861.3 eV, which matched the Ni²⁺ in NiWO₄, the Ni²⁺ species oxidation state and the satellite peak, respectively. Similarly, in the Ni 2p_{1/2} region, three peaks are located at 869.2, 874.2 and 880.1 eV, which originated from the Ni²⁺ in NiWO₄, the Ni²⁺ species oxidation state and the satellite peak.⁴⁶ In Fig. 4(E), the W 4f spectrum can be deconvoluted into well-resolved spin orbit split dou-

blet peaks at 35.7 and 37.8 eV,^{37,47} which correspond to W 4f_{7/2} at 35.7 eV and W 4f_{5/2} at 37.8 eV, with a spin energy separation of 2.1 eV which is consistent with the previous report for W⁶⁺.³⁷ Besides, both the W 4f_{7/2} peak at 35.7 eV and the Ni 2p_{3/2} peak at 855.9 eV demonstrate the formation of a Ni tungstate binary metal oxide. From the O 1s spectrum in Fig. 4(F), we can see that there is a major peak located at 531.9 eV,⁴⁷ which is ascribed to the lattice oxygen in the NiWO₄ phase indicating the presence of NiWO₄.⁴⁷

3.2.2 BET analysis. The physical adsorption properties of the samples are of great importance not only for the

Fig. 4 XPS patterns of the [CdS/NiWO₄ (30%)] sample. (A) Survey, (B) S 2p, (C) Cd 3d, (D) Ni 2p, (E) W 4f and (F) O 1s scan spectra.

realization of improved sample performance, but also for affecting the catalytic reaction. The adsorption and desorption properties of the samples rely on their specific surface area, pore volume and pore size. In order to obtain the nitrogen adsorption and desorption isothermal curves, pore size distri-

bution curves and physical adsorption desorption performance parameters of the samples, we utilize the ASAP 2020 M instrument at 77 K to carry out the experiment, whose results are shown in Fig. 5(A and B) and Table 1. From Fig. 5(A), we can observe that the adsorption/desorption

Fig. 5 (A) The N₂ adsorption-desorption isotherms and (B) corresponding pore size distribution curves.

Table 1 The physical adsorption performance parameters

Samples	S_{BET}^a (m ² g ⁻¹)	Pore volume ^b (cm ³ g ⁻¹)	Average pore size ^b (nm)
CdS	27	0.20	24.0
NiWO ₄	190	0.18	4.1
CdS/NiWO ₄ (30%)	66	0.18	11.1

^a Obtained from the BET method. ^b Relative pressure (P/P_0) was 0.99.

curves of CdS nanorods, NiWO₄ and [CdS/NiWO₄ (30%)] belong to the type IV isotherm, whose hysteresis loop is of the H3 type. We can draw a conclusion from Fig. 5(B) that the three materials are mesoporous materials on the basis of the pore size distribution curve and the average pore size.

On further analysis of Table 1, we can see that the specific surface area of pure CdS nanorods and NiWO₄ is 27 and 190 m² g⁻¹, respectively. At the same time, we can see that the pure CdS nanorods have a larger average pore size, reaching 24.0 nm, and that NiWO₄ has a minimum average pore size

of 4.1 nm. When 30% of NiWO₄ is loaded onto the surface of CdS nanorods, the specific surface area of the composite catalyst [CdS/NiWO₄ (30%)] is between those of CdS nanorods and NiWO₄, which indicates that NiWO₄ has been successfully loaded onto the surface of CdS nanorods, which is beneficial to the photocatalytic reactions.

3.2.3 UV-vis DRS analysis. Light absorption performance is of great importance in influencing the H₂ production activity. Therefore, we use a diffuse reflectance spectrometer to test the photoresponse behavior of the samples. Fig. 6(A) shows

Fig. 6 (A) The UV-vis diffuse reflectance spectra; (B) the plot of transformed Kubelka-Munk function vs. the energy.

that the pure CdS nanorods have prominent optical absorption in the UV and visible light regions exhibiting an absorption edge located at 525 nm, and that NiWO₄ has outstand-

ing optical absorption in the UV and visible light regions. In addition, three absorption bands (240–360 nm, 400–460 nm and 650–750 nm) of NiWO₄ can be clearly seen,⁴⁸ which are

Fig. 7 (A–C) The H₂ production activity curves of CdS nanorods, NiWO₄ and [CdS/NiWO₄ (x%)] (x = 5, 10, 30, 50, 70) in 30 ml 10% lactic acid solution; (D) stability test on the [CdS/NiWO₄ (30%)] sample; (E) the AQE of the [CdS/NiWO₄ (30%)] sample in 30 ml 10% lactic acid solution.

caused by the oxidation state of the cations, in agreement with those reported in the literature by M. M. Mohamed and assigned to the NiWO₄ formation.⁴⁸ For [CdS/NiWO₄ (x%)] (x = 5, 10, 30, 50, 70), on the one hand, the absorption edge becomes larger, that is to say, their absorption edge has a tendency to red shift;⁴² on the other hand, the light absorption intensity is enhanced in the wavelength range from 600 to 800 nm.

In order to obtain the energy band gap (E_g) of the samples, we draw the Tauc graph from the UV-vis diffuse reflectance spectra. The E_g is estimated by the function (eqn (2)):

$$(\alpha h\nu)^{1/2} = A(h\nu - E_g)$$

α – the absorption coefficient;
 h – Planck's constant (incident photon energy);
 ν – the frequency of radiation;
 A – a constant;

(2)

From CdS nanorods to [CdS/NiWO₄ (70%)], the E_g values are estimated to be 2.32, 2.26, 2.30, 2.28, 2.27, 2.25 and 2.36 eV, respectively. It may be the different colors of the samples and different percentages of NiWO₄ that lead to different light absorption intensities. The light absorption intensity of the photocatalyst increases with the increase of the percentage of NiWO₄. Nevertheless, excessive loading of NiWO₄ on the surface of CdS nanorods will prevent CdS from absorbing visible light,⁴¹ thereby reducing the photocatalytic H₂ production activity.

3.3 Photocatalytic H₂ evolution performance

In order to test the photocatalytic H₂ production performance and the stability of the samples, they are tested in a 10% lactic acid solution, and the results are shown in Fig. 7. We break down Fig. 7(A) into Fig. 7(B) and (C) so that we can study the H₂ production performance of CdS nanorods and NiWO₄ and the effect of different percentages of NiWO₄ on the H₂ production performance. From Fig. 7(B), we can see that pure NiWO₄ did not produce H₂ within 5 h, which means that pure NiWO₄ has no photocatalytic H₂ production activity. The H₂ production of CdS nanorods for 5 hours is the smallest, reaching 103 μ mol, due to the rapid recombination of photogenerated electrons and holes. When 30% NiWO₄ is deposited on the surface of CdS nanorods, by testing, the H₂ production amount reaches the maximum of 757 μ mol, which is 7.35 times higher than that of CdS nanorods.

In order to study the effect of the content of NiWO₄ on the H₂ production activity, we test the H₂ production performance of the different percentages of the composite catalyst [CdS/NiWO₄ (x%)] (x = 5, 10, 30, 50, 70) prepared above, and the results are shown in Fig. 7(C). The hydrogen yield of the composite catalysts exhibits the shape of an arch bridge, that is, as the percentage content of NiWO₄ increases, the amount of H₂ production also increases. The amount of H₂ production reaches the maximum (757 μ mol, 5 h) when the percentage content of NiWO₄ is 30%. Subsequently, when the per-

centage of NiWO₄ is continuously increased, the amount of hydrogen production begins to decrease gradually. This may be attributed to the phenomenon that superfluous NiWO₄ not only can absorb more visible light by itself, but also can occupy some active sites of CdS nanorods, thus inhibiting the H₂ production activity.⁴¹

Further, in order to evaluate the stability of catalyst activity, the [CdS/NiWO₄ (30%)] sample is selected to be tested in a 10 vol% lactic acid solution. We perform a total of 5 cycles of 5 hours each. When the end of each cycle is ended, the reaction system is replaced with N₂ to remove hydrogen from the last cycle. In Fig. 7(D), we can see that the total amount of H₂ in each cycle is almost equal and the slight decrease in hydrogen production in the fifth cycle may be due to lactic acid consumption, which indicates that the catalyst activity is relatively stable. Further, we test the AQE of the [CdS/NiWO₄ (30%)] composite catalyst at different wavelengths. The results are shown in Fig. 7(E): it can be seen that as the monochromatic wavelength increases, the AQE also increases, and the AQE reaches 15.5% when the monochromatic wavelength is 475 nm. When a larger monochromatic wavelength is used, the AQE begins to decrease; when the monochromatic wavelength is up to 550 nm, the AQE is only 0.4%, indicating that the catalyst produces little H₂ at this wavelength. When the wavelength of monochromatic light is 600 nm, the AQE is 0, indicating that the wavelength cannot excite the [CdS/NiWO₄ (30%)] composite catalyst.

We can draw conclusions from the above analysis results: the p-n type heterojunction between CdS nanorods and NiWO₄ is successfully formed; under the internal electric field and potential difference, the electron and hole migration speeds are accelerated, thus improving the H₂ production performance of the composite catalyst.

3.4 Separation mechanism of charge transfer

3.4.1 PL spectra and TRPL spectra. The separation and transfer of charge and the lifetime of electrons and holes are of great importance in elucidating the possible charge separation and transfer mechanisms. Therefore, photoluminescence experiments and fluorescence lifetime decay experiments are carried out. The results are shown in Fig. 8 and Table 2. Fig. 8(A and C) show the photoluminescence (PL) spectra of CdS nanorods, [CdS/NiWO₄ (5%)], [CdS/NiWO₄ (30%)], [CdS/NiWO₄ (70%)] and NiWO₄. In Fig. 8(A), the PL spectra of all the samples present a parabolic shape with different intensities. Their emission wavelength center is approximately 520 nm while the excitation wavelength is 380 nm. In Fig. 8(C), when the excitation wavelength is 290 nm, the emission wavelength of NiWO₄ nanoparticles ranges from 300 to 550 nm, which is similar to other wolframite compounds.³² It is the WO₆⁶⁻ anion along with some defects in the crystal structure that determines the fluorescence emission peak of NiWO₄.³² The emission peak at 350 nm is from the band gap transition. The doublet peaks appear at 382 and 395 nm, which are due to either the quantum size⁴⁹ or to the interference between

Fig. 8 (A and C) The PL spectra and (B) the time-resolved photoluminescence (TRPL) spectra.

Table 2 The exponential curve fitted parameters of emission decay for the samples

Samples	T_1 [ns]	A_1 [%]	T_2 [ns]	A_2 [%]	T_3 [ns]	A_3 [%]	χ^2	τ_{ave} [ns]	K_{ET} [10^9 s^{-1}]	$\eta_{(\text{inj})}$ [%]
CdS	5.60	22.11	0.69	17.58	160.4	60.31	1.89	3.96	—	—
CdS/NiWO ₄ (70%)	5.32	22.67	0.59	17.75	150.8	59.58	1.90	2.90	0.092	26.7
CdS/NiWO ₄ (5%)	5.24	22.96	0.55	18.56	149.5	58.48	1.91	2.58	0.135	34.8
CdS/NiWO ₄ (30%)	4.44	25.90	0.41	19.54	101.7	54.65	2.02	1.87	0.282	52.7

the luminescence band of the WO₆ groups and the absorption band of the NiO₆ groups.⁵⁰ The other obvious emission peaks appear at 435, 466 and 480 nm, which are related to the intensive transition from the ground state $^3A_{2g}$ to the excited state 3T_1 of Ni²⁺ (3d⁸) ions in a distorted octahedral coordination³² or due to recombination of e–h pairs localized at oxygen-atom-deficient tungstate ions.⁵¹ Compared with that of CdS nanorods, the emission peak fluorescence intensity of NiWO₄ is the strongest, which indicates that it has the highest degree of combination of electrons and holes. When different amounts of NiWO₄ are adhered to the surface of CdS nanorods, the fluorescence intensity of the emission peaks is quenched to varying degrees. As the percentage of NiWO₄ increases, the emission peak intensity first decreases and then increases, and the emission peak of [CdS/NiWO₄ (30%)] is the

weakest and quenched to the maximum extent. Based on the above results, we can further draw the conclusion: the p–n junction and an internal electric field between NiWO₄ and CdS are formed. It is the internal electric field that accelerates the rapid separation and transfer of electrons and holes, thereby effectively enhancing the photocatalytic activity of H₂ production.

What's more, time-resolved photoluminescence (TRPL) is a promising approach to observe the kinetics of electron transfer and further study the separation and transfer of photogenerated electrons and holes. In Fig. 8(B), the decay curves of the samples are fitted by a triexponential decay function (eqn (3)).²⁷ The composite catalysts demonstrate a faster TRPL decay compared with CdS nanorods, which indicates efficient charge separation.

$$I(t) = \sum_{i=1,2,3} B_i \exp(-t/\tau_i)$$

I – the normalised emission intensity;
 t – the time after the pulsed laser excitation;
 B_i – the amplitude (pre-exponential factor);
 τ_i – the TPRL decay time;

(3)

From the fitting parameters in Table 2, it can be seen that the short lifetime (T_1 , T_2) and long lifetime (T_3) gradually reduce. We use eqn (4)²⁷ to calculate the average lifetime (τ_{ave}) so that we can better understand the effect of NiWO₄ content on the decay life of the composite catalysts.

$$\langle \tau \rangle = \sum_{i=1,2,3} B_i \tau_i^2 / \sum_{i=1,2,3} B_i \tau_i$$

$\langle \tau \rangle$ – the average lifetime;
 B_i – the amplitude (pre-exponential factor);
 τ_i – the TPRL decay time;

(4)

The average lifetime of CdS nanorods, [CdS/NiWO₄ (70%)], [CdS/NiWO₄ (5%)] and [CdS/NiWO₄ (30%)] is 3.96, 2.90, 2.58 and 1.87 ns, respectively. Generally speaking, the shorter the electron lifetime, the faster the electron transfer rate. The above results reflect the transfer of electrons from CdS nanorods to NiWO₄ in a relatively short period of time. Using the average lifetime of the samples, we further calculate the electron transfer rate constant (K_{ET})⁵² and the electron injection efficiency (η_{inj})^{53,54} using eqn (5) and (6) respectively:

$$K_{ET} = \frac{1}{\tau_{ave}(\text{sample})} - \frac{1}{\tau_{ave}(\text{CdS})}$$
(5)

$$\eta_{inj} = 1 - \frac{\tau_{ave}(\text{sample})}{\tau_{ave}(\text{CdS})}$$
(6)

Based on the above formula, from [CdS/NiWO₄ (5%)] to [CdS/NiWO₄ (30%)], the electron transfer rate constant (K_{ET}) and electron injection efficiency (η_{inj}) are calculated to be 0.092×10^9 , 0.135×10^9 , 0.282×10^9 s⁻¹ and 31.4, 36.9 and 44.7%, respectively. Therefore, the above results further prove that the p-n type heterojunction between NiWO₄ and CdS is successfully formed. It's the p-n heterojunction that makes the electrons rapidly transfer from the conduction band (CB) of NiWO₄ to that of CdS in a relatively short time, further participating in the process of H₂ production.

3.4.2 Photoelectrochemical (*i-t* and EIS) analysis. It is well known that the photoelectric properties of catalysts are also important factors affecting the separation and transfer of electrons and holes. Photocurrent density-time experiments (*i-t*) and AC impedance experiments (EIS) were conducted to

determine the photoelectric properties of the samples. To this end, we carry out the above experiments in 0.2 M Na₂SO₄ aqueous solution.

Fig. 9(A) shows the photocurrent density-time curve of CdS nanorods, NiWO₄ and [CdS/NiWO₄ (*x*%) (*x* = 5, 10, 30, 50, 70)]. In order to observe the photocurrent response of NiWO₄ clearly and intuitively, we deconvolute the photocurrent response of NiWO₄ in Fig. 9(A), and the result is shown in Fig. 9(B). It can be seen that NiWO₄ nanoparticles have the lowest photocurrent density, and that the photocurrent density of pure CdS nanorods is improved to some extent compared to that of NiWO₄ nanoparticles. Further, considering Fig. 9(A and B), it can be concluded that the photocurrent density of the pure CdS nanorods is 16.24 times higher than that of the NiWO₄ nanoparticles. When NiWO₄ is loaded onto the CdS nanorods, the photocurrent density of the composite catalyst is improved. After 5 cycles of light on/off, the photocurrent density of the composite catalyst showed a downward trend, which may be due to the existence of certain photo-corrosion of CdS under light conditions in 0.2 M Na₂SO₄ aqueous solution. On further observation, it can be found that with the increase of NiWO₄ content, the photocurrent density of the composite catalyst also increases; when the loading of NiWO₄ reaches 30%, the photocurrent density is the largest; when the content of NiWO₄ continues to increase, the photocurrent density begins to decrease. The photocurrent density results of the above samples correspond to the photocatalytic hydrogen production activity shown in Fig. 7(A).

The AC impedance spectroscopy (EIS) technique can be used to qualitatively study the migration ability of electrons in a photoanode film and the electron exchange capability between the photoanode and the electrolyte interface. Fig. 9(C) shows the AC impedance spectrum of CdS nanorod, NiWO₄ and [CdS/NiWO₄ (*x*%) (*x* = 5, 10, 30, 50, 70)] photoelectrodes in dark state. The smaller the arc radius, the smaller the interface charge transfer resistance. The arc radius of [CdS/NiWO₄ (30%)] is the smallest, which means that the conductivity of the [CdS/NiWO₄ (30%)] photoelectrode is outstanding. The illustration shows the equivalent circuit diagram. The solution resistance (R_{sol}), the transfer resistance of photogenerated electrons in the photoelectrode material (R_{film}) and the interfacial reaction resistance (R_{ct}) together constitute the AC impedance value of the photoelectrode. In addition, Q represents the original phase angle; C represents the interface capacitance. The fitted EIS data of CdS and [CdS/NiWO₄ (30%)] are shown in Table 3. It can be seen from the fitting results in Table 3 that the R_{film} of the CdS nanorods modified by NiWO₄ decreased from 2.77×10^4 Ω cm² to 2785 Ω cm², which is about 10 times lower; the R_{ct} decreased from 11.43 Ω cm² to 1.74 Ω cm²; C is increased from 9.43×10^{-5} μF cm⁻² to 3.2×10^{-3} μF cm⁻², indicating that the surface state density of the NiWO₄ modified CdS nanorods has increased significantly. The above results indicate that the interface electric

Table 3 The parameters of potentiostatic EIS fitted by ZsimpWin

Samples	R_{sol} [Ω cm ²]	Q [Ω^{-1} cm ² s ⁿ]	n	R_{film} [Ω cm ²]	W_{ss} [Ω cm ²]	C [μ F cm ⁻²]	R_{ct} [Ω cm ²]
CdS nanorods	25.86	2.36×10^{-5}	0.927	2.77×10^4	1.53×10^{-5}	9.43×10^{-5}	11.43
CdS/NiWO ₄ (30%)	23.99	8.24×10^{-5}	0.854	2785	1.01×10^{-5}	3.2×10^{-3}	1.74

field formed between NiWO₄ and CdS nanorods enhances the separation of electrons and holes, thereby effectively suppressing charge recombination.

3.5 Potential reaction mechanism

When NiWO₄ is combined with CdS nanorods, it will cause the change of the energy level potential, thereby establishing a new interface electric field. The Mott-Schottky method test is based on the function of capacitance and scanning potential. Fig. 10 shows the Mott-Schottky curves of CdS nanorods and NiWO₄ photoelectrodes. Their flat band potential can be determined by eqn (7):

$$1/C^2 = 2(N_D e \epsilon \epsilon_0)^{-1} \cdot (E - E_{fb} - \kappa T/e)$$

C – the capacitance of the space charge region;
 N_D – charge carrier concentration;
 e – electron charge;
 ϵ_0 – vacuum permittivity;
 ϵ – dielectric constant of CdS and NiWO₄;
 E – electrode applied potential;
 E_{fb} – flat band potential;
 T – absolute temperature;
 κ – Boltzmann constant;

(7)

Fig. 10 Mott-Schottky plots of (A) n-type CdS nanorods and (B) p-type NiWO₄ at a frequency of 5.0 kHz.

Along the linear portion of the Mott-Schottky curves of CdS nanorods and NiWO₄, the tangent is extended to the abscissa. We can not only see that the flat-band potential of CdS nanorods and NiWO₄ is -0.61 and 2.44 V *versus* SCE, respectively, but also see that CdS nanorods and NiWO₄ are an n-type semiconductor with a positive slope and a p-type semiconductor with a negative slope, respectively.⁵⁵ Generally speaking, for an n-type semiconductor, the E_{CB} is more negative by about -0.1 or -0.2 V than the E_{fb} ; for a p-type semiconductor, the E_{VB} is more positive by approximately 0.1 or 0.2 V than the E_{fb} .^{55,56} Therefore, the E_{CB} of CdS nanorods and E_{VB} of NiWO₄ are sketchily calculated to be -0.81 and 2.64 V *vs.* SCE. Based on the formula: $E_{NHE} = E_{SCE} + 0.241$, the E_{CB} of CdS nanorods and E_{VB} of NiWO₄ are calculated to be -0.569 and 2.881 V *vs.* NHE.

The p-n heterojunction formed between NiWO₄ and CdS nanorods is of great importance in promoting the separation of electrons and holes. The Mulliken electronegativity theory (eqn (8) and (9))^{36,57} is used to estimate the VB and CB band positions of NiWO₄ and CdS nanorods so that we can thoroughly understand the formation of the p-NiWO₄/n-CdS heterojunction and the energy band structure.

$$E_{VB} = \chi - E^e + 0.5E_g \quad (8)$$

$$E_{CB} = E_{VB} - E_g \quad (9)$$

where χ is the absolute electronegativity of the semiconductor, which is the geometric mean of the electronegativity of the constituent atoms. The E_g of NiWO₄ and CdS is given in Fig. 6(B), and is 2.26 and 2.32 eV, respectively. The χ values of NiWO₄ and CdS are determined to be 6.301 (ref. 58) and

5.075 eV,³⁶ respectively. E^e is the energy of free electrons on the hydrogen scale (4.5 eV *vs.* NHE). Table 4 lists the calculated band positions according to the above formula and relevant data. Through comparison and analysis, the band positions obtained from the Mott-Schottky plot results are close to the calculated ones in Table 4.

Through the above analysis results, we have drawn the energy band position diagram. Fig. 11 shows the band positions of p-NiWO₄ and n-CdS before and after contact. At the same time, Fig. 11 and Scheme 1 describe the charge migration process and the photocatalytic reaction process. As a p-type semiconductor, NiWO₄'s VB position is more positive and its Fermi level is close to the VB position. However, CdS nanorods are an n-type semiconductor; CdS nanorods' CB position is more negative and its Fermi level is close to the CB position. When NiWO₄ is loaded on CdS nanorods, the Fermi level potential of CdS is more negative than the negative potential of NiWO₄, which provides a thermodynamic path to promote charge transfer, making the electrons diffuse from the CB of CdS to the CB of NiWO₄, resulting in negative charge accumulation in NiWO₄. At the same time, holes migrate from the VB of NiWO₄ to the VB of CdS nanorods, resulting in the accumulation of positive charges in the CdS nanorods until their Fermi levels are equal. During the Fermi level shifting, the energy bands of the NiWO₄ and CdS nanorods move up and down as the Fermi level moves until the two Fermi levels reach equilibrium. Finally, at equilibrium, an internal electric field from the CdS to NiWO₄ direction is established at the interface between NiWO₄ and CdS nanorods. Under visible light irradiation, CdS and NiWO₄ can be excited to generate electrons and holes. Subsequently, under the action of the potential difference and the internal electric field, electrons can

Table 4 The absolute electronegativity, band gap energy, and valence and conduction band edge potential of CdS and NiWO₄

Semiconductor	Absolute electronegativity (χ)	Band energy E_g (eV)	Valence band E_{VB} (eV)	Conduction band E_{CB} (eV)
CdS (n-type)	5.075	2.32	1.74	-0.58
NiWO ₄ (p-type)	6.301	2.26	2.93	0.67

Scheme 1 Photocatalytic mechanism of the CdS/NiWO₄ system.

be rapidly transferred from the CB of NiWO₄ to the CB of the CdS nanorods, and further migrated to the surface of the CdS nanorods to participate in the reduction of protons to produce H₂. At the same time, photogenerated holes migrate from the VB of CdS nanorods to the VB of NiWO₄, further migrate to the surface of NiWO₄, and then oxidize lactic acid to produce CO₂ and H₃O⁺, thereby effectively promoting the separation of electrons and holes, and improving the photocatalytic H₂ production efficiency of the composite catalyst.

4. Conclusions

In conclusion, a highly-efficient CdS/NiWO₄ p-n heterojunction composite catalyst is successfully constructed. In the composite catalyst, the introduction of NiWO₄ simultaneously improves the photocatalytic H₂ production performance of CdS nanorods and the stability of photocatalytic H₂ production. The photocatalytic H₂ production properties of the CdS/NiWO₄ composite catalyst are closely related to the loading capacity of NiWO₄. The [CdS/NiWO₄ (30%)] sample has the best H₂ production performance. Under visi-

ble light irradiation, the maximum H₂ production in 5 hours is 757 μmol, which is 7.35 times higher than that of pure CdS nanorods. Further studies of photoluminescence spectra, photoelectrochemistry experimental results and Mott-Schottky curves show that the modification of NiWO₄ enhances the electron mobility and charge transfer ability of the composite catalyst. However, excessive NiWO₄ will reduce the light absorption intensity of CdS nanorods, thereby reducing the hydrogen production activity. It is the built-in electric field formed between NiWO₄ and CdS nanorods that accelerates the separation of photogenerated electrons and holes. At the same time, the photogenerated holes on the VB of CdS nanorods can be quickly transferred to the surface of NiWO₄, which slows down the photo-corrosion of CdS.

Author contributions
