DOI: 10.1039/d3fd00161j

We develop a coupled-cluster full-dimensional global potential energy surface (PES) for the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  reactive system, using the Robosurfer program package, which automatically samples configurations along PES-based trajectories as well as performs *ab initio* computations with Molpro and fitting with the monomial symmetrization approach. The analytical PES accurately describes both the bimolecular nucleophilic substitution ( $\text{S}_{\text{N}}2$ ) and elimination (E2) channels leading to the  $\text{Cl}^- + \text{CH}_3\text{CH}_2\text{OH}$  and  $\text{Cl}^- + \text{H}_2\text{O} + \text{C}_2\text{H}_4$  products, respectively, and allows efficient quasi-classical trajectory (QCT) simulations. QCT computations on the new PES provide accurate statistically-converged integral and differential cross sections for the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  reaction, revealing the competing dynamics and mechanisms of the  $\text{S}_{\text{N}}2$  and E2 (*anti*, *syn*,  $\beta$ - $\alpha$  transfer) channels as well as various additional pathways leading to induced inversion of the  $\text{CH}_3\text{CH}_2\text{Cl}$  reactant, H-exchange between the reactants,  $\text{H}_2\text{O}\cdots\text{Cl}^-$  complex formation, and  $\text{H}_2\text{O} + \text{CH}_3\text{CHCl}^-$  products *via* proton abstraction.

## 1. Introduction

Bimolecular nucleophilic substitution ( $\text{S}_{\text{N}}2$ ) is probably the best-known type of ion–molecule reaction, especially in organic chemistry. The simplest examples of these processes are the  $\text{X}^- + \text{CH}_3\text{Y}$  reactions, where X and Y are halogens.<sup>1–4</sup> As we move beyond the reactions of methyl-halides, a new, so-called bimolecular elimination (E2) channel becomes possible and competes with the  $\text{S}_{\text{N}}2$  reaction. The prototypes of these reactions are  $\text{X}^- + \text{CH}_3\text{CH}_2\text{Y}$ , which lead to  $\text{Y}^- + \text{CH}_3\text{CH}_2\text{X}$  *via*  $\text{S}_{\text{N}}2$  and  $\text{Y}^- + \text{HX} + \text{C}_2\text{H}_4$  with E2.<sup>5–12</sup> Thermodynamically the  $\text{S}_{\text{N}}2$  channel is

usually favored, however, kinetic control cannot decide about the expected outcome of the competition between the  $S_N2$  and E2 pathways.<sup>9–11</sup> Comprehensive dynamics investigations of the  $S_N2/E2$  reactions have been lacking due to the complexity of these systems until very recently. In the past few years the Wester group studied  $S_N2/E2$  processes using a crossed-beam technique combined with velocity map imaging.<sup>9,11,13,14</sup> These experiments provided unprecedented insights into the competing dynamics of the  $S_N2/E2$  reactions, however, the direct measurement for the two channels separately was not possible, because these experiments could only detect the ionic products, which are the same ( $Y^-$ ) for both reactions.<sup>9,11,13,14</sup> Therefore, dynamics simulations were needed to disentangle the competing channels. The traditional theoretical approach for  $S_N2$  reactions is direct dynamics, where the electronic structure computations of the forces are performed on-the-fly during the quasi-classical trajectory (QCT) computations. This approach was applied to the  $F^- + CH_3CH_2I$  reaction by Hase and co-workers in 2017.<sup>9</sup> However, direct dynamics simulations are very time consuming, thus, only a low-level of electronic structure theory can be employed and only a few trajectories can be computed, especially for these large  $S_N2/E2$  systems. Therefore, it was a real breakthrough that in 2021 we could develop a full-dimensional analytical potential energy surface (PES) for the  $F^- + CH_3CH_2Cl$  reaction, which allowed efficient dynamics simulations.<sup>11</sup> In collaboration with the Wester group, we revealed that E2 dominates over  $S_N2$  in the  $F^- + CH_3CH_2Cl$  reaction, which finding was explained by the wider range of reactive attack angles for the former process.<sup>11</sup>

The above-described dynamics investigations motivated several recent studies on the  $F^- + CH_3CH_2Y$  [ $Y = Cl, Br, I$ ] reactions.<sup>15–19</sup> Moreover, theoretical studies on the more complex  $OH^- + CH_3CH_2Y$  [ $Y = F, Cl, Br, I$ ] systems have also been started very recently.<sup>17,20,21</sup> In 2021 our group characterized the stationary points of the  $OH^- + CH_3CH_2Y$  reactions for  $Y = F, Cl, Br,$  and  $I$  using a high-level explicitly-correlated coupled-cluster method.<sup>20</sup> In 2022 Xie and co-workers<sup>21</sup> investigated the competing  $S_N2$  and E2 mechanisms for the microsolvated  $OH^-(H_2O)_{n=0-4} + CH_3CH_2Y$  [ $Y = Cl, Br, I$ ] reactions using the CCSD(T)/PP/t//MP2/ECP/d level of theory. In 2023 Zhang and co-workers<sup>17</sup> reported MP2/aug-cc-pVDZ computations to study the effect of nucleophiles on the  $S_N2/E2$  competition in the  $X^- + CH_3CH_2Cl$  [ $X = F, Cl, Br, I,$  and  $OH$ ] reactions. Despite the above-mentioned previous work, a “dynamical simulation study” of these reactions “is lacking” as also mentioned in ref. 21. Therefore, in the present study we report a full-dimensional high-level *ab initio* analytical PES for the 10-atom  $OH^- + CH_3CH_2Cl$  system utilizing the Robosurfer program package,<sup>22</sup> thereby moving beyond our previous  $S_N2$  dynamics studies of 5–9-atom reactions.<sup>4,11,23–26</sup> The new PES enables efficient QCT simulations for the competing  $S_N2$  and E2 channels and even beyond as we describe in the next sections of this article.

## 2. Computational details

The first task is to obtain an initial PES. We take the benchmark geometries<sup>20</sup> of this 10-atom system and create new geometries by randomly distorting the structures and scattering the fragments (if there are multiple ones). For the reactants and products, we generate 500, while for the minima and transition states in the interaction region, 250 random data points and perform single-point

energy computations. For these computations, we use a composite *ab initio* method. The core of this is the explicitly-correlated coupled-cluster singles and doubles (CCSD-F12a) method,<sup>27</sup> with the aug-cc-pVDZ basis set.<sup>28</sup> The next term is a Brueckner-type<sup>29</sup> parenthesis T correction (see explanation in ref. 24), while the basis set remains the same:

$$\delta(T) = \text{BCCD}(T)/\text{aug-cc-pVDZ} - \text{BCCD}/\text{aug-cc-pVDZ}. \quad (1)$$

Lastly, we have a TZ basis-set correction term, calculated as the difference between the energies of the explicitly-correlated second-order Møller-Plesset perturbation (MP2-F12) method<sup>30</sup> with aug-cc-pVTZ and aug-cc-pVDZ basis sets:

$$\delta\text{TZ} = \text{MP2-F12}/\text{aug-cc-pVTZ} - \text{MP2-F12}/\text{aug-cc-pVDZ}. \quad (2)$$

In summary, we obtain the energies as the following:

$$E_{\text{composite}} = \text{CCSD-F12a}/\text{aug-cc-pVDZ} + \delta(T) + \delta\text{TZ}. \quad (3)$$

For the *ab initio* computations, we use the Molpro program package.<sup>31</sup> Out of the 7000 initial computations, 6520 converged. We also set a maximal relative energy limit, 150 kcal mol<sup>-1</sup>, with respect to the global minimum: the points over that are excluded, leaving 4108 points in the starter set. The PES fitting is accomplished by the monomial symmetrization approach (MSA) of the permutationally invariant polynomial method.<sup>32</sup> At the beginning, we do a fourth-order fitting with 2143 coefficients. To improve the accuracy, we utilize the Robosurfer program system,<sup>22</sup> which iteratively improves the fitting dataset by running test quasi-classical trajectories and choosing potential geometries to have their single-point energies computed with Molpro and to be added to the dataset. The total number of these iterations is 304, while we gradually increase the collision energy ( $E_{\text{coll}}$ ) in the trajectories (1, 5, 10, 20, ..., 80 kcal mol<sup>-1</sup>) and increase the fitting to the fifth order. In the final version, we have a permutationally-invariant fifth-order analytical PES as a function of  $\exp(-r_{ij}/a)$  variables, where  $a = 3.0$  bohr and  $r_{ij}$  are interatomic distances, with 19 322 data points and 11 581 coefficients. The coefficients are obtained by a weighted linear least-squares fit to the energy points using a weight function of  $E_0/(E_0 + E)$ , where  $E_0 = 0.15$  hartree and  $E$  is the potential energy relative to the global minimum of the dataset (RMS). The root-mean-square fitting errors are 1.91, 3.17, 2.03 and 2.04 kcal mol<sup>-1</sup> in the 0.00–94.13, 94.13–188.25, 188.25–470.63 and 470.63– kcal mol<sup>-1</sup> intervals, relative to the global minimum, respectively.

On the newly-developed potential energy surface we run quasi-classical trajectory simulations and analyze the results to study the dynamics of the title reaction. We set up each trajectory by giving the reactants zero-point energy (ZPE), *via* setting the system to the quasi-classical ground vibrational state by the standard normal-mode sampling.<sup>33</sup> We also randomly orient the reactants with a distance of  $\sqrt{x^2 + b^2}$  between them, where  $x$  is 28.3 bohr (15 Å) and  $b$  is the impact parameter. We constantly increase the value of the impact parameter from 0.0 with a 0.5 bohr step size until  $b_{\text{max}}$ , which value will result in no reactive trajectories. The last parameter we need to address is the  $E_{\text{coll}}$  collision energy, we have seven different values for that: 1, 5, 10, 20, 30, 40 and 50 kcal mol<sup>-1</sup>. At every

Fig. 1 The definitions of the initial attack angles:  $\alpha_1$  is the angle between the  $C_\alpha$ -Cl bond vector and the center of mass velocity vector of the ethyl chloride while  $\alpha_2$  is the angle between the O-H bond and the center of mass velocity vector of the hydroxide ion.

$b$ - $E_{\text{coll}}$  combination, we run a thousand trajectories, resulting in 204 000 final trajectories. We propagate them with a 0.0726 fs time step until the largest interatomic distance is longer by 1 bohr than the initial largest interatomic distance. Note that this condition causes a negligible error for the trajectories resulting in bimolecular eliminations, as there could be a remaining interaction energy term: it is not guaranteed that all three fragments separate well enough, yet we assume the fragments are not in interaction at the end of the simulations. As it affects about 1% of the trajectories, it will not influence the results. We calculate reaction probabilities and excitation functions (integral cross sections (ICSS) as a function of  $E_{\text{coll}}$ ) for the different reaction channels. For the most prevalent reactions, we do further calculations. First, we determine the ICSSs with soft and hard ZPE restrictions. Soft restriction means that we exclude trajectories where the total vibrational energy of the products is lower than the sum of their ZPEs, while in the case of hard restrictions, the vibrational energy of every product separately has to reach the corresponding ZPE value. Note, that in the case of these calculations, we treat the different channels together, so the total number of trajectories compiling with the ZPE restrictions will be the same for every reaction. This can result in a larger restricted ICSS, than without the constraints, if there are other channels with a high number of ZPE violating trajectories, while the investigated channel has a low number of these kinds of trajectories. Additionally, we determine the scattering and the initial attack angle distributions (the definitions of the two attack angles can be seen in Fig. 1), relative translational energy distributions of the products and the internal energy distributions of every product molecule/ion.

### 3. Results and discussion

#### 3.1. Short description of the PES

We summarize the relative energies of the most important stationary points in Table 1 and the interested reader can find the vibrational frequencies of the reactants and products in Table S1 of the ESI.† The difference between the PES and benchmark<sup>20</sup> relative energies is composed of two parts: one term is caused by the difference in the level of theory, while the second term is the fitting error. The first term can be described by the difference between the composite and benchmark relative energies, which is 0.8 kcal mol<sup>-1</sup> on average. There is also the

**Table 1** Classical energies (kcal mol<sup>-1</sup>) of the stationary points for the OH<sup>-</sup> + CH<sub>3</sub>CH<sub>2</sub>Cl system, relative to the reactants, obtained by composite and benchmark *ab initio* computations as well as on the PES

<sup>a</sup> Relative energies obtained by the composite method (CCSD-F12a/aug-cc-pVDZ + BCCD(T)/aug-cc-pVDZ - BCCD/aug-cc-pVDZ + MP2-F12/aug-cc-pVTZ - MP2-F12/aug-cc-pVDZ) used for the PES development. <sup>b</sup> Relative energies obtained on the analytical PES. <sup>c</sup> Benchmark relative energies obtained at the CCSD(T)-F12b/aug-cc-pVQZ level of theory taken from ref. 20.

fitting error ( $E_{\text{composite}} - E_{\text{PES}}$ ) which is 1.5 kcal mol<sup>-1</sup> on average for these stationary points, 0.9 kcal mol<sup>-1</sup> if we consider the products only. These values are consistent with the RMS fitting error of the PES (2–3 kcal mol<sup>-1</sup> in these regions, as discussed in Section 2).

The  $T_1$ -diagnostic<sup>34</sup> values at the stationary points are only 0.013 on average, not considering the reactants and products, where we do not expect any significant multi-reference character. The largest  $T_1$  value is found for the FSTS, which is still not greater than 0.025. Based on these  $T_1$  results, we can conclude that single-reference electronic structure methods are adequate to describe the PES of the title reaction.

We schematically illustrate the most important region of the PES, the stationary points belonging to the S<sub>N</sub>2 and E2 reaction channels, in Fig. 2. The PES relative energies of these points are in good agreement with the benchmark results<sup>20</sup> as mentioned before, the shape of the PES well describes the reactions. The S<sub>N</sub>2 can proceed *via* several transition states: namely the double-inversion TS (DITS), the Walden TS (WaldenTS) and the front-side TS (FSTS). The DITS eventually turns into the WaldenTS and follows the same path. Comparing the TSs, the WaldenTS is the most favored one. Front-side attack has a unique minimum, FSMIN, while the other two channels go through PreMIN, whereas the S<sub>N</sub>2 PostHMIN structures are shared between the three paths, leading to the products. The E2 reaction can follow two main pathways with special transition states and minima: the *anti*- or the *syn*-E2. The difference is arising from the orientation of

Fig. 2 The schematic energy diagram of the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$   $\text{S}_{\text{N}}2$  and E2 reactions; the classical relative energies ( $\text{kcal mol}^{-1}$ ) obtained on the PES developed in this work are in comparison with the benchmark, CCSD(T)-F12b/aug-cc-pVQZ single-point results (ref. 20).

the nucleophile and the leaving group at the stationary points: consider a plane that is perpendicular to the C–C–Cl plane and it crosses the two carbon atoms. In the *anti* case the nucleophile and the leaving group are on the different sides of this plane, while for the *syn* instance, they are on the same side. Kinetically, the *anti*-E2 is favored as the *anti*-E2 TS is deeper than the *syn*-E2 TS. The *syn*-E2 path can also lead to the formation of ethylene and a chloride ion–water complex (before forming the E2 products), with a dissociation energy of  $15 \text{ kcal mol}^{-1}$ , which means that this product is stable enough that it could be observed even experimentally. Comparing the  $\text{S}_{\text{N}}2$  and E2 channels it is evident that the  $\text{S}_{\text{N}}2$  is the thermodynamically favored one by  $15 \text{ kcal mol}^{-1}$ , but it is difficult to determine which reaction is favored kinetically as the energy difference between the *anti*-E2 TS and the Walden TS is less than  $1 \text{ kcal mol}^{-1}$ .

As long range ion–dipole interactions play an important role in the entrance channel of the title reaction, in Fig. 3 we show the potential energy curve along the O–C $_{\alpha}$  distance corresponding to collinear back-side-attack configurations. As seen, the composite energies agree very well with the benchmark CCSD(T)-F12b/aug-cc-pVQZ results. Furthermore, the PES values also fit accurately on the benchmark/composite potential and its long-range behavior is well reproduced.

### 3.2. Possible reactions (and mechanisms) in the simulations, integral cross sections

We have managed to identify six different reactions within our simulations, some with different mechanisms. The first two reactions are the induced inversion and the H-exchange. In these cases, if we investigate the chemical composition at the beginning and at the end of the trajectories, seemingly, nothing happens; we could classify them as non-reactive trajectories. However, if we have an induced-inversion reaction, as its name suggests, the stereochemistry of the ethyl chloride reactant

Fig. 3 Potential along the O–C<sub>α</sub> distance of OH<sup>−</sup> + CH<sub>3</sub>CH<sub>2</sub>Cl keeping the reactants at fixed equilibrium geometries obtained by the CCSD(T)-F12b/aug-cc-pVQZ and composite (eqn (3)) *ab initio* levels of theory as well as on the analytical PES.

will change. As the hydroxide ion approaches the ethyl chloride interacts with it (partially abstracts a proton from C<sub>α</sub>, which eventually bonds back), inverting the steric orientation around C<sub>α</sub>, and then the two reactants separate. The H-exchange reaction is similar; however, a different proton gets re-bonded and the steric change is not necessarily present in this reaction. In Fig. 4, we illustrate the most important steps of this reaction: at first, the reactants approach each other and then the OH<sup>−</sup> interacts with an α-hydrogen, a proton abstraction happens, and a water molecule forms. However, there is not enough energy in the reactants to separate, the water orbits around the remnant anion. After a while, another proton abstraction will happen, but this time the CH<sub>3</sub>CHCl<sup>−</sup> abstracts from H<sub>2</sub>O. As the final step, the new ethyl chloride and the new hydroxide ion get isolated. We can say “new”, because if we follow the indices of the H atoms, we can see that the proton from the initial OH<sup>−</sup> gets abstracted back to form the final CH<sub>3</sub>CH<sub>2</sub>Cl. Experimentally, they are indistinguishable, but using deuterium (isotope substitution on one of the reactants) could be a solution to investigate this reaction. The exchange only happens on C<sub>α</sub>, the proton abstraction from C<sub>β</sub> would eventually lead to E2 reaction.

The two reactions with the highest probabilities are the S<sub>N</sub>2 and the E2. For both channels we observed that the main reaction could be preceded by an H-exchange reaction (only from C<sub>α</sub>). The stereospecificity of the S<sub>N</sub>2 reactions shows us what we expected from the energy diagram: the reactions mostly occur *via* Walden inversion, as retention only takes place in a negligible number of trajectories. The bimolecular elimination reactions mainly happen *via* the *anti*-E2 path, as it is kinetically more favored, rather than the *syn*-E2 one, but there is a third mechanism as well, although with minor presence. We call this the β–α transfer mechanism, shown in Fig. 5. The reactants come into contact and a proton abstraction happens from C<sub>α</sub>. The H<sub>2</sub>O distances itself, while the anion is rearranged. A proton from the C<sub>β</sub> is shared between the two carbon atoms,

Fig. 4 The main steps of the H-exchange reaction in the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  system. The dashed line means that the species are well separated in space. (I) The reactants approach each other. (II) A proton abstraction (H3) occurs from  $\text{C}_\alpha$  (C7), forming water. (III) The newly-formed  $\text{H}_2\text{O}$  orbits around the remnant fragment. (IV) The water reaches the anion and a new  $\text{C}_\alpha\text{-H}$  (C7-H1) bond is formed while the original O-H (O9-H1) bond breaks. (V) The ethyl chloride and the hydroxide ion distance themselves.

Fig. 5 The main steps of the E2 reaction in the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  system with the  $\beta\text{-}\alpha$  transfer mechanism. The dashed line means the species are well separated in space. (I) The reactants approach each other. (II) A proton abstraction (H2) occurs from  $\text{C}_\beta$  (C7), forming water. (III) The newly-formed  $\text{H}_2\text{O}$  orbits around the remnant fragment. (IV) The water leaves the remnant anion, the  $\text{C}_\alpha\text{-Cl}$  (C7-Cl10) bond gets elongated, while a proton (H4) interacts with both of the carbon atoms. (V) The  $\text{C}_\alpha\text{-Cl}$  (C7-Cl10) bond breaks, a chloride ion leaves, the original  $\text{C}_\beta\text{-H}$  (C8-H4) bond breaks, while a new  $\text{C}_\alpha\text{-H}$  (C7-H4) bond is formed, leading to ethylene.

Fig. 6 Integral cross sections of the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  reaction channels at collision energies up to  $50.0 \text{ kcal mol}^{-1}$  (except the E2 ( $\beta$ - $\alpha$  transfer)), as a function of collision energy.

while the  $\text{C}_\alpha$ -Cl bond is elongated. Finally, the  $\text{C}_\alpha$ -Cl bond breaks and the shared proton gets bonded to the  $\text{C}_\alpha$  atom, forming ethylene.

The last two reactions are the formation of the chloride ion-water complex and the proton abstraction (H-Abs). The  $\text{H}_2\text{O} \cdots \text{Cl}^-$  complex product forms *via* the *syn*-E2 reaction path, on a longer timescale it would definitely dissociate into water and chloride ion, but we detect these as products. The H-Abs reaction is simple, the proton is abstracted from  $\text{C}_\alpha$ , as the abstraction from the  $\beta$  carbon leads to the E2 reaction. In addition, there is no trajectory where an H-exchange would precede the abstraction reaction.

The ICSs of the aforementioned reactions are plotted in Fig. 6 and the corresponding numerical data are given in Table S2.<sup>†</sup> E2 reaction appears to be the dominating one, while the  $\text{S}_{\text{N}}2$  has about five times less ICS. The other reactions also have reasonable ICSs, they are not small, but the E2 and the  $\text{S}_{\text{N}}2$  ones are extremely large. We can see that the values drop with increasing  $E_{\text{coll}}$  (except for H-Abs), which is expected if we consider the barrier-less exothermic nature of the processes. H-exchange reactions are significant both independently and as a predecessor of E2/ $\text{S}_{\text{N}}2$  reactions. The E2 reactions are mainly proceeding *via* the *anti*-E2 path, but over  $30 \text{ kcal mol}^{-1}$   $E_{\text{coll}}$ , the dominance is not so accentuated. From  $20 \text{ kcal mol}^{-1}$  collision energy, H-Abs is more likely to happen than  $\text{S}_{\text{N}}2$ , becoming the second most probable reaction.

### 3.3. $\text{S}_{\text{N}}2$ QCT results

In Fig. 7, we can see the final QCT results regarding the  $\text{S}_{\text{N}}2$  channel. Observing the reaction probabilities ( $P(b)$ ) we can see a decrease in the maximal impact parameter values up to  $20$ – $30 \text{ kcal mol}^{-1}$  collision energies, from that, it somewhat stagnates. The  $b_{\text{max}}$  decrease with increasing  $E_{\text{coll}}$  is a key feature of the barrier-less, exothermic reactions. At lower collision energies, the long-range ion-dipole interactions have time to build up, produce a reactive orientation, attract the reactants together, but with increasing  $E_{\text{coll}}$  (thus velocities), the time is shorter, the species might just by-pass each other, hence the overall decrease in the reaction probabilities. The ICS curves show us an interesting phenomenon: with soft or hard restrictions, we have higher values. This can be explained by the

Fig. 7 Final QCT results for the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  reaction's  $\text{S}_{\text{N}}2$  channel: reaction probabilities ( $P(b)$ ), integral cross sections with three different restrictions (for more information about the restrictions, see Computational details), normalized scattering angle distributions ( $\cos(\theta)$ ), normalized initial attack angle distributions ( $\cos(\alpha_1)$  and  $\cos(\alpha_2)$ ) (for the definitions, see Fig. 1), normalized product relative translational energy distributions ( $E_{\text{trans.}}$ ) and normalized product internal energy distributions ( $E_{\text{int.}}$ ).

fact that there are practically no ZPE violating trajectories at this channel (for definitions, see Section 2), which is expected, as this reaction is very exothermic (the reaction heat is  $-51.57 \text{ kcal mol}^{-1}$  on the PES). However, the ZPE violation of the other channels decreases the total number of trajectories thereby indirectly increasing the  $\text{S}_{\text{N}}2$  reactivity.

At low collision energies, we have quite isotropic scattering angle ( $\cos(\theta)$ ) curves, which is a sign of indirect reactions, we have both backwards scattering (rebound mechanism,  $-\cos(\theta)$  region) and forward scattering (stripping mechanism,  $+\cos(\theta)$ ). At higher collision energies, we have a more direct reaction as the backward scattering becomes more dominant, *via* the direct rebound mechanism, as expected for the  $\text{S}_{\text{N}}2$  reaction channel. The  $\cos(\alpha_1)$ , C-Cl attack angle plots also show us that at low  $E_{\text{coll}}$  values we have isotropy, as the reaction is indirect and the reactivity is nearly independent of the initial reactant orientation, because the ion-dipole interactions can guarantee the success of the chemical reaction. As we increase the collision energy, the front-side attack ( $+\cos(\alpha_1)$ ) does not lead to reactive trajectories, because the reactions happen *via* the WaldenTS and not *via* the FSTS. At large  $E_{\text{coll}}$  the reaction becomes more direct with back-side attack ( $-\cos(\alpha_1)$ ) preference, again, which can be explained by the fact that the ion-dipole interactions cannot orient the

ethyl chloride. The O–H ( $\cos(\alpha_2)$ ) attack angles show an interesting behavior: we would expect an increasing O-side preference with increasing collision energy, since the new chemical bond will form between a carbon atom and the oxygen, but that is not the case. The curves are practically isotropic in the whole  $E_{\text{coll}}$  regime, we can say there is a slight decrease in the H-side preference, but that shape can be due to the increasing statistical errors as the ICS drops at higher collision energies (leaving us with less reactive trajectories). The isotropic feature implies that the ion–dipole interaction can orient the  $\text{OH}^-$  even at high collision energies, the hydroxide ion behaves like a simple, spherical ion without a specific structure. The difference between the ethyl chloride and the  $\text{OH}^-$  attack angle distributions can be reasoned by comparing their moments of inertia. The former one is a large, bulky molecule, with relatively high moments of inertia, thus it takes more time and/or stronger forces to orient it, while the latter is a small and light ion with much less inertia, and can be easily rotated rapidly even at higher collision energies by the ion–dipole interactions.

Looking at the translational energy distributions ( $E_{\text{trans.}}$ ), the first observation that can be made is that with increasing  $E_{\text{coll}}$ , the reactants separate with increasing translational energies. Not only the maximal values change with the collision energies, but the shape of the curves too: at low  $E_{\text{coll}}$ , we have the maxima at lower  $E_{\text{trans.}}$  values, but as we increase  $E_{\text{coll}}$ , we get hotter and hotter curves, where the maxima are shifted towards the middle and right sides of the energy regimes. This means that the available energy in the system gets more and more transferred to the translational part with increasing collision energy, which is connected with the fact that the reaction becomes more direct. The internal energy ( $E_{\text{int.}}$ ) distributions show the complementary behavior: the curves become colder and colder, the sharp right shoulder, which can be clearly seen at low  $E_{\text{coll}}$ , gets more and more shifted to the middle region of the internal energy curves with increasing  $E_{\text{coll}}$ . Previously, considering the ICS curves with restrictions, we stated that there are no ZPE violations for the  $\text{S}_{\text{N}}2$  reaction, and this fact is also in accord with the internal energy distributions, as the ZPE of the ethyl alcohol on our PES is  $50 \text{ kcal mol}^{-1}$ , which is way below the minimal internal energy values. Comparing the translational and internal energy curves at  $E_{\text{coll}} = 1 \text{ kcal mol}^{-1}$  (which is practically negligible), we can see that the reaction heat mainly gets transferred into internal energy (the translational energy is very cold), while with increasing  $E_{\text{coll}}$  the collision energy gets distributed between the two terms roughly equivalently (the maxima shift roughly by the same amount for both energy types).

### 3.4. E2 QCT results

The results of the trajectory analysis for the E2 reaction channel can be seen in Fig. 8. We have also separated the results by mechanisms using the same technique as in ref. 12, the summary of the *anti*-E2 reactions can be seen in Fig. 9, while the *syn*-E2 results are illustrated in Fig. 10. Note that, in general, we have many fewer trajectories with the latter mechanism, resulting in higher statistical errors for the plots. We describe the results for the sum of the two mechanisms, but we also highlight the differences between them.

The reaction probability is the highest for the E2 channel at the collision energies investigated in this study. On average, it is 3–4 times more likely that a trajectory ends up in the E2 reaction, than in the  $\text{S}_{\text{N}}2$  one, however, the  $b_{\text{max}}$

**Fig. 8** Final QCT results for the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  reaction's E2 channel (for the mechanism-specific results see Fig. 9 and 10): reaction probabilities ( $P(b)$ ), integral cross sections with three different restrictions (for more information about the restrictions, see Computational details), normalized scattering angle distributions ( $\cos(\theta)$ ), normalized initial attack angle distributions ( $\cos(\alpha_1)$  and  $\cos(\alpha_2)$ ) (for the definitions, see Fig. 1), normalized product relative translational energy distributions ( $E_{\text{trans}}$ ) and normalized product internal energy distributions ( $E_{\text{int}}$ ) (for both ethylene and water).

values are very similar, these are only 0.5–1.0 bohr higher for E2. If we compare the probabilities of the two E2 mechanisms (Fig. 9 and 10), we can notice that the dominant one is the *anti* pathway, however, from  $E_{\text{coll}} = 30 \text{ kcal mol}^{-1}$  they become comparable, getting closer and closer to each other. Due to the smaller number of *syn*-E2 trajectories, it is important to note that the results for that mechanism are burdened with more statistical error. The probability of *anti*-E2 drops rapidly up to  $30 \text{ kcal mol}^{-1}$  collision energy, after that, the decrease slows down. In the case of *syn*-E2, the maximal probability is the lowest at  $1 \text{ kcal mol}^{-1}$   $E_{\text{coll}}$  with the highest  $b_{\text{max}}$  value. If we increase the collision energies the maximal probability gets higher and the maximal impact parameter gets lower, however, over  $5 \text{ kcal mol}^{-1}$   $E_{\text{coll}}$ , we cannot observe significant changes. The E2 ICSS tell us that there are ZPE violations, as the unrestricted values are higher than the ones with either soft or hard restrictions. The difference between the two constrained curves suggests that one product systematically has lower energy than ZPE, but if we use the soft restriction, the vibrational energy of the other product can compensate the missing energy.

Fig. 9 Final QCT results for the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  reaction's *anti*-E2 channel: reaction probabilities ( $P(b)$ ), normalized scattering distributions ( $\cos(\theta)$ ), normalized initial attack angle distributions ( $\cos(\alpha_1)$  and  $\cos(\alpha_2)$ ) (for the definitions, see Fig. 1), normalized product relative translational energy distributions ( $E_{\text{trans}}$ ) and normalized product internal energy distributions ( $E_{\text{int}}$ ) (for both ethylene and water).

The scattering angle shows us similar, but not as significant behavior (for both mechanisms, with more statistical error for *syn*) than in the case of  $\text{S}_{\text{N}}2$ : we cannot observe direct correlation between the collisional energy and the forward scattering preference, but a feature of this reaction, the forward scattering, can be seen in the curves. Inspecting the overall C–Cl attack angle distributions, we can see that as the reaction becomes more direct, the curves lose the isotropy. This transition is not as harsh as in the case of the  $\text{S}_{\text{N}}2$  reaction, it can explain why the results show much larger reaction probabilities for E2: the E2 reaction can happen in a much broader attack angle interval. The main difference between the *anti*- and the *syn*-E2 can be seen here: the shape of the  $\cos(\alpha_1)$  curves indicates that for *anti* there is a back-side attack preference, while for *syn* front-side attack is preferred. These findings are straightforward in light of the structures of the *anti*-E2 and *syn*-E2 transition states (Fig. 2). The  $\cos(\alpha_2)$  distributions show the same findings as for  $\text{S}_{\text{N}}2$  in both cases: we would expect an O-side attack preference, but the  $\text{OH}^-$  acts as a “spherical” ion, we can only observe a marginal agreement with our expectations at the two highest  $E_{\text{coll}}$ .

If we increase the collision energy, it will increase the product relative translational energy. The maxima of the translational energy curves are shifted with the extra  $E_{\text{coll}}$ , while the internal energies show minimal dependence on this

Fig. 10 Final QCT results for the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  reaction's *syn*-E2 channel: reaction probabilities ( $P(b)$ ), normalized scattering angle distributions ( $\cos(\theta)$ ), normalized initial attack angle distributions ( $\cos(\alpha_1)$  and  $\cos(\alpha_2)$ ) (for the definitions, see Fig. 1), normalized product relative translational energy distributions ( $E_{\text{trans}}$ ) and normalized product internal energy distributions ( $E_{\text{int}}$ ) (for both ethylene and water).

parameter (especially the  $E_{\text{int}}$  of the water product). The energy curves do not show a remarkable change in the overall shape, meaning that there is no straight transition from indirect to direct aspects (similarly to the E2 scattering angle distributions). The ZPEs of the ethylene and the water are about 32 and 14 kcal mol<sup>-1</sup> on the PES, respectively, and the reaction is less exothermic than S<sub>N</sub>2, thus we expect more trajectories to be excluded because of the constraints. Considering the former values and the internal energy plots, we can see slight ZPE violations for the ethylene and more significant problems for H<sub>2</sub>O. Approximately half of the E2 trajectories violate the hard restrictions because the water does not have enough vibrational (and internal) energy, as predicted from the ICS plot earlier. Analyzing the contrast between E2 with the two different mechanisms, we can conclude that there is a modestly better energy transfer to the internal energies in the case of the *syn*-E2.

### 3.5. H-Abs QCT results

As already discussed in Section 3.2, we also note here that the proton abstraction happens from C<sub>α</sub> in every case in the simulations (as abstraction from C<sub>β</sub> would end up in an E2 reaction). The plots belonging to the proton-abstraction reaction can be seen in Fig. 11. Note that these data might have the highest uncertainty as the

**Fig. 11** Final QCT results for the  $\text{OH}^- + \text{CH}_3\text{CH}_2\text{Cl}$  reaction's proton-abstraction channel: reaction probabilities ( $P(b)$ ), integral cross sections with three different restrictions (for more information about the restrictions, see Computational details), normalized scattering angle distributions ( $\cos(\theta)$ ), normalized initial attack angle distributions ( $\cos(\alpha_1)$  and  $\cos(\alpha_2)$ ) (for the definitions, see Fig. 1), normalized product relative translational energy distributions ( $E_{\text{trans}}$ ) and normalized product internal energy distributions ( $E_{\text{int}}$ ) (for both the  $\text{CH}_3\text{CHCl}^-$  anion and water).

smallest amount of reactive trajectories belongs to this channel (considering the ones that are being analyzed in more detail). The  $P(b)$  shows a general increase at small impact parameters until we reach  $30 \text{ kcal mol}^{-1}$  collision energy, while the  $b_{\text{max}}$  value drops rapidly and remains the same (7.5–8.0 bohr) from the same  $E_{\text{coll}}$ . From that point, the reaction probability becomes comparable with that of E2, and overcomes the  $\text{S}_{\text{N}}2$  reactivity. The shape of the ICS curves completely changes with the constraints, a threshold energy appears, as the reaction itself is endothermic, thus the products are not available at low collision energies unless ZPE violation happens. We consider the soft- and hard-constrained curves to be more realistic.

The reaction starts as isotropic regarding the scattering angle distributions, but as the collision energy increases, the forward scattering nature prevails, the stripping mechanism becomes dominant; the hydroxide ion strips the proton and moves forward. The  $\cos(\alpha_1)$  distributions pinpoint a back-side attack preference even at low  $E_{\text{coll}}$ , as the hydrogens on the  $\text{C}_\alpha$  are more accessible from that direction. For the O–H attack angle distribution, we have the same conclusions as before: the  $\text{OH}^-$  will be rapidly rotated into the reactive orientation thanks to its small moment of inertia, in contrast to the expected O-side domination, we see isotropic curves.

Considering the relative translational energy plots, we can conclude that the shape of the curves changes with increasing  $E_{\text{coll}}$ , suggesting that the reaction becomes more direct. The internal energy distributions show us that the additional energy with the higher collision energies gets transferred both into the  $E_{\text{trans}}$  and  $E_{\text{int}}$ , in the latter case more into the internal energy of the product anion. The ZPEs on the PES are roughly 41 and 14 kcal mol<sup>-1</sup> for the larger ionic fragment and the water, respectively. For this channel, we have a large number of ZPE violating trajectories. This phenomenon can be seen not only in the ICS plot, but also in the internal energy diagrams: only a small segment of the curves is beyond the zero-point energy limit for each product.

## 4. Summary and conclusions

We have developed a full-dimensional reactive potential energy surface for the OH<sup>-</sup> + CH<sub>3</sub>CH<sub>2</sub>Cl reaction based on energy points belonging to a widespread of possible reaction channels. The PES fitting was done using the monomial symmetrization approach (MSA) of the permutationally invariant polynomial method.<sup>32</sup> The PES was iteratively improved using the Robosurfer program package.<sup>22</sup> The level of theory was chosen to be a composite level: an explicitly-correlated coupled-cluster method (CCSD-F12a) with the aug-cc-pVDZ basis set, along with Brueckner-type (T) and MP2-F12 triple-zeta corrections. We performed over 200 000 QCT simulations at different impact parameters with different collision energies in the range of 1–50 kcal mol<sup>-1</sup>. At those setups, we could identify six different reactions: induced inversion, H-exchange, H<sub>2</sub>O...Cl<sup>-</sup> complex formation, proton abstraction, S<sub>N</sub>2 and E2. We also investigated the mechanisms and processes preceding the formation of the products in the above-mentioned reactions, as well as determined the reaction probabilities and excitation functions. For the last three (and most probable) reactions we performed a detailed analysis to achieve a deeper understanding of the reactions: we calculated the ICSs with different restrictions, scattering and two types of attack angle distributions, product relative translational and product internal energy distributions. These results can promote the investigation of the OH<sup>-</sup> + CH<sub>3</sub>CH<sub>2</sub>Cl system experimentally and/or the PES can be used for simulations at different conditions, even looking at other aspects of the dynamics than in the present work.

## Data availability

The data that support the findings of this study are available from the corresponding author upon reasonable request.

## Conflicts of interest

There are no conflicts of interest to declare.

## Acknowledgements

We thank the National Research, Development and Innovation Office–NKFIH, K-125317 and K-146759; Project no. TKP2021-NVA-19, provided by the Ministry of Innovation and Technology of Hungary from the National Research, Development

and Innovation Fund, financed under the TKP2021-NVA funding scheme; and the Momentum (Lendület) Program of the Hungarian Academy of Sciences for the financial support. The authors are also thankful to Viktor Tajti for his help with the PES development.
