The electronic structure of transition metal oxides for oxygen evolution reaction

Hongxia Wang,^a Kelvin H. L. Zhang,^b*^a Jan P. Hofmann,^b Victor A. de la Peña O'Shea^c and Freddy E. Oropeza^c*^c

Electrolysis of water to produce hydrogen and oxygen is a promising pathway for the storage of renewable energy in form of chemical fuels. The efficiency of the overall process is usually limited by the sluggish kinetics of the oxygen evolution reaction (OER) due to a complex four-electron/proton transfer mechanism. Therefore, the most crucial step for water electrolysis to become a widespread industrial process is to develop efficient electrocatalysts capable of driving the OER at a low overpotential. In this article, we present a review of the recent understanding of low-cost transition metal oxide-based catalysts for electrochemical OER. Our main focus is on the fundamental understanding of the electronic structure of these materials and its relationship with the catalytic activity and the reaction mechanism. We detail the electronic structure descriptors of the OER performance that have provided guidelines for the development of advanced electrocatalysts. Strategies to enhance the activity based on such electronic structure guidelines, including doping, strain and defect engineering are also discussed. Finally, we summarize the existing challenges and present perspectives for the future development of the field.

1. Introduction

Since the 19th century, non-renewable energy resources such as coal, oil, and natural gas have been utilized as the main energy

supply to sustain human activities.¹ However, the excessive consumption of fossil fuels caused by the rapidly increasing world population and expanding industrialization as well as concomitant environmental problems have motivated our society to explore a green and sustainable energy system for long-term development.^{2–5} In this regard, countries around the world have made gigantic efforts to raise the share of renewable and carbon-free sources of energy, such as solar, wind, and tidal energy.⁶ Unfortunately, these energy sources have a general intermittent availability and heavily depend on the season and weather, which result in a low energy delivery efficiency and

Hongxia Wang received her master degree in chemistry and chemical engineering from Chongqing University in 2020. She is currently a PhD candidate at college of Chemistry and Chemical Engineering, Xiamen University under the supervision of Prof. Kelvin H. L. Zhang. Her research interest focusses on the synthesis of clean and efficient materials and their applications in electrochemical energy storage and conversion.

Kelvin H. L. Zhang is a professor at college of Chemistry and Chemical Engineering, Xiamen University. His current research interest focus on the synthesis and properties of complex metal oxide thin films and heterostructures relevant to application in oxide electronics and electrocatalysts. He obtained his PhD degree in chemistry of Oxford University in 2012, followed by working as a postdoc at

Pacific Northwest National Laboratory and as a Herchel Smith Fellow at University of Cambridge from 2015 to 2017.

restrict their widespread application. Thus, the storage of renewable energy in the form of fuels and useful chemicals is a highly valuable approach to introduce such sources of renewable energy in the mainstream of our current energy economy. In this regard, hydrogen has been considered as a promising energy carrier because it has zero-carbon combustion products and the highest gravimetric energy density.^{7,8} Hydrogen not only can be used as energy carrier itself but it is also an important industrial feedstock for methanol production and ammonia synthesis among other processes. Since technologies for the conversion of many sources of renewable energy (e.g., solar irradiance and wind) into electrical power are well-developed these days, the electrochemistry provides means of storing the surplus of solar- or wind-driven electricity into fuels and valuable chemicals with a low carbon

footprint.⁹ In a joint effort, scientists, policymakers and politicians around the world have carried extensive research and investment on projects for the large-scale wind power or photovoltaic hydrogen production, which combining the utilization of renewable energy with the hydrogen generation through water electrolysis.¹⁰ Currently, the global hydrogen production reaches more than 110 Mt per year.¹¹ However, the H₂ production through water electrolysis only takes 4% of whole hydrogen supply,¹² because the high cost to drive the electrolytic water splitting (>US\$4 per kg of H₂) compared with the hydrogen production cost through the reforming of fossil fuels (US\$1.3–1.5 per kg of H₂).¹¹ The cost of industrial water electrolysis mainly arises from the large electric energy input required, which is closely related with the composition of applied catalysts and their catalytic performance.¹³ Thus, developing cheap catalysts with high activities is significant to reduce the production cost with better economic benefits (<US\$2 per kg of H₂) and broaden the commercial and industrial application of electrochemical water splitting.

Since Troostwijk and Diemann firstly observed the phenomenon of water electrolysis in 1789,¹⁴ it has been extensively investigated by researchers over the past years. It is now well-established that water electrolysis involves two fundamental half reactions: hydrogen evolution reaction (HER) at the cathode, and the oxygen evolution reaction (OER) at the anode. Driving the electrochemical water splitting thermodynamically requires to overcome the energy barrier of 237.2 kJ mol⁻¹ at standard conditions, which corresponds to an applied voltage of 1.23 V in an electrochemical cell.^{15,16} However, in practice, the actual applied cell voltage is much larger than the theoretical value due to the overpotentials required to drive both the HER and the OER.¹⁷ As a result, even in well-developed and optimised water electrolysis systems, such as proton-exchange membrane water electrolyzers for electrolysis in acidic condition (Fig. 1), a voltage of 1.7–2.2 V is required to deliver a current density of >1.6 A cm⁻².¹⁸ The situation is similar in anion-

Jan Philipp Hofmann is full professor of Surface Science at Technical University of Darmstadt, Germany since 2020. He received his chemistry diploma and doctoral degree from Justus-Liebig University (JLU) in Gießen, Germany in 2005 and 2009, respectively. After a 1 year post-doctoral stay at JLU Giessen with Prof. Herbert Over, in 2011, he moved to the Netherlands to become DFG postdoc fellow in the

Debye Institute of Nanomaterials Science (group of Prof. Bert M. Weckhuysen) at Utrecht University. From 2013–2020, he has been assistant professor of Inorganic Materials Chemistry and Solar Fuels Catalysis at Eindhoven University of Technology, NL. His research focuses on the energetics, chemistry, and dynamics of interfacial processes in energy materials and devices.

Victor A. de la Peña O'Shea received his PhD in Physical Chemistry (2003) from the Universidad Autonoma de Madrid and the Catalysis and Petrochemistry Institute (Spain). After his PhD, he spent three years at Universidad de Barcelona, where he got the M.Sc. in Physics. In 2008, he moved to IMDEA Energy, where he is the head of the photoactivated processes unit. He has co-

authored over 120 publications, several patents, and books. He has coordinated more than 25 research projects, including an ERC-CoG. His research group is focused in the design and development of novel multifunctional materials and reactors applied to sustainable energy and environmental technologies.

Freddy E Oropeza is a Marie Skłodowska-Curie fellow at IMDEA Energy. His research interests focus on the understanding and control of the structural and electronic properties that define the functionality of metal oxide thin films and interfaces for applications in electronics and (photo)electrochemical technologies. He obtained his PhD in Chemistry from the University of Oxford in

2012, followed by working as postdoc at the Ruhr University Bochum (2012–2013), Imperial College London (2013–2016) and the Eindhoven University of technology (2016–2019).

Fig. 1 Schematics of the electrochemical water splitting in anion-exchange membrane electrolyser and proton-exchange membrane electrolyser.

exchange membrane electrolyzers for electrolysis in alkaline media (Fig. 1) in which a voltage of 1.7–2.4 V is usually required to deliver a current density of $<1.0 \text{ A cm}^{-2}$.¹⁹ Most of the overpotential loss comes from the OER that involves a multi-step transfer process of electrons and protons with a complex reaction mechanism, resulting in sluggish kinetics and larger activation energy barriers than those associated to the HER process.²⁰ In this scenario, developing more active catalysts toward the OER has become the most important factor to improve the overall efficiency of water electrolysis for industrial applications.

After decades of efforts, the worldwide research for OER catalysts have made significant progress in promoting the catalytic activities. Numerous novel materials have emerged as advanced OER catalysts such as metal chalcogenide,^{21–23} oxides,^{24,25} nitrides^{26,27} and molecular/polymeric systems.^{28,29} Ru- and Ir-based oxides are OER catalysts of high industrial relevance because their high activity in acidic media and implementation in proton-exchange membrane electrolyzers.^{30,31} However, both RuO₂ and IrO₂ undergo further oxidation and subsequent dissolution in acidic electrolytes under high applied potentials,^{32,33} leading to unstable performance during water electrolysis. Furthermore, the high price of Ru and Ir also inhibit their large-scale application. On the other hand, one of the major advantages of alkaline water electrolysis over the acidic electrolysis is the replacement of conventional noble metal electrocatalysts with low-cost transition metal (TM) catalysts. Additionally, an alkaline media provides higher stability for the OER metal oxide catalysts.^{19,34} Nevertheless, the anion-exchange membrane electrolysis is still a developing technology, and the current density and voltage efficiency achieved are lower than those in the electrolysis in acidic media. Therefore, considering the cost and activity for the practical utilization, extensive research efforts must be focused on investigating earth-abundant transition metal oxide (TMO) electrocatalysts including perovskite family,^{35,36} spinel family,^{37–39} layer-structured hydroxides^{40–42} and other types of

oxides.^{43,44} The OER performance of reported outstanding TMOs have exhibited remarkable activities and relatively high electrochemical stability, especially in alkaline electrolytes.^{45–47}

In order to develop a competitive low-cost anion-exchange membrane electrolysis technology for commercially viable hydrogen production, further research and improvements are required, specifically regarding the reaction mechanisms on the surface of the catalysts and the development of guidelines for the preparation of advanced OER electrodes. Earlier in 1955, Rüttschi and Delahay reported an approximate linear relationship between the rate of the OER on metal oxides and the M–OH binding strength.⁴⁸ They made the pioneering attempt to link the OER activity with a descriptor. Furthermore, in the 1970s, Matsumoto *et al.*⁴⁹ firstly studied the correlation between the OER catalytic activity of perovskite oxides and their band structure. They proposed that the perovskite-type oxide formed σ^* and π^* band, and the rate of electron transfer would increase with the rise of the σ^* bandwidth. Later, Bockris and Otagawa systematically investigated the OER activities on perovskite oxides and they connected the OER activity with the number of electrons occupied in the antibonding orbitals.⁵⁰ Based on the band structure theory and molecular orbital theory, a few typical descriptors have been recently proposed to link the activity with electronic structure and thus theoretically predict the catalytic activity of novel catalysts. The most notable electronic descriptors of the OER activity include the number of electrons in the e_g orbitals of metal cations,^{51,52} the degree of TM 3d–O 2p hybridization,⁵³ the energy position of the O 2p band center,⁵⁴ charge-transfer energy,³⁵ bulk thermochemistry⁵⁵ among others. For instance, Shao-Horn and co-workers systematically studied the relation between OER activities and the number of e_g electrons for perovskite oxides, conducting a conclusion that the optimal catalytic performance could be achieved when the number of electrons filled in e_g orbital was 1.2.⁵¹ Later, Xu *et al.*⁵⁶ reported that e_g orbital occupancy correlates well with the OER activity of spinel type oxides. Zhou *et al.*⁵⁷ and Xie *et al.*⁵⁸ report that the activity can be optimized by adjusting the

spin state of Co 3d orbital electron in the LaCoO₃ system. Moreover, Grimaud *et al.*⁵⁹ also use the position of O 2p-band centre relative to the Fermi level as a descriptor of the OER catalytic activities. The investigations on the correlation of the OER catalytic activity with electronic structure have provided meaningful results. A comprehensive understanding of these

Table 1 The performance of various TM oxide electrocatalysts for the OER

Fig. 2 Crystal structure of common TM oxides for OER: (a) perovskite, (b) spinel, and (c) LDH structure.

descriptors could help us rationally design TM oxide catalysts with improved performance for the OER and push forward for further developments in this field.

In this review, we provide an overview of the recent progress of the researches on OER catalysts and the generally proposed reaction mechanisms along with the emphasis on the correlation between oxide electronic structures and OER activity. We firstly introduce the most common TM oxide electrocatalysts studied for alkaline water electrolysis along with some recent reports of outstanding catalytic performances, and the main reaction mechanisms that have been proposed for the OER on TM oxides. Then, the electronic structure descriptors in TM oxides for the OER electrochemical activity are discussed, followed by a review on material science strategies to tailor the electronic structure parameters for the design of highly active electrocatalysts. Finally, we briefly conclude the review and discuss the challenges and opportunities for the future development of TM oxides. The in-depth comprehension of the correlation between the OER activity and electronic structure of TM oxide catalysts can be instructive to explore future generation catalysts, and connects the research fields of heterogeneous catalysis with the solid-state chemistry and physics.

2. TM oxide electrocatalysts for alkaline OER

A major advantage of the anion-exchange membrane water electrolysis over the proton-exchange membrane electrolysis is the replacement of conventional noble metal electrocatalysts, such as the traditional Ir- and Ru-based oxides, with low-cost TM oxides. Additionally, the alkaline media provides higher stability to the OER metal oxide catalysts. Since the TMs in the oxide have significant contribution to the valence states of the material, the physicochemical properties are strongly susceptible to the type and chemistry (*e.g.*, oxidation state, coordination and spin state) of the TM. This property provides TM oxides with large flexibility for the design of electrocatalysts for the OER. As a result, many metal oxides have been suggested as

promising OER catalysts in alkaline media over the last decade.^{20,60} Table 1 provides a comparison of the performance of various TM oxides electrocatalysts for the OER recently reported in the literature, which provides context to the current state of the art. Although TM oxides in a wide range of compositions are currently under investigation, most can be grouped into complex perovskite oxides, spinel oxides or layered (oxy)hydroxides.

2.1 Perovskite TM oxides

Perovskite TM oxides are attractive electrocatalysts for promoting the OER because of their tuneable electronic structure and high activity.⁶¹ Perovskite oxides have a general ABO_3 structure, with rare-earth and/or alkaline large cations at the A site that have a 12-fold coordination with oxygen anions, and TMs at the B site in the centre of a corner-sharing octahedra of oxygen anions, see Fig. 2a. The chemistry of the TM in the B site can be widely modulated by substitution at A site, *e.g.*, La^{3+} for Sr^{2+} , which provides means to tailor the OER catalytic properties of the oxides.^{51,61} Well-known examples of this approach are the systems $Sr_xLa_{1-x}FeO_3$ and $Sr_xLa_{1-x}CoO_3$ with $0 \leq x \leq 1$, in which the substitution of La^{3+} for Sr^{2+} induces the oxidation of the TM at the B site, leading to improvements of the catalytic activity for the OER.^{54,62,63}

2.2 Spinel oxides

Spinel oxides have also been shown to drive the OER with excellent catalytic performances.⁶⁴ These oxides have the general chemical formula AB_2O_4 and a crystalline structure in which TM cations in tetrahedral (cation A) and octahedral sites (cation B) coexists, as depicted in Fig. 2b. Such arrangement provides multiple sites for accommodating different transition-metal cations and in a wide range of valence states, allowing therefore the preparation of a wide variety of oxides.^{64,65} The possibility for TM cations in both the tetrahedral and octahedral sites to be involved in the OER may bring ambiguities as to which site is responsible for the OER catalysis. However, theoretical and experimental studies have specifically addressed this issue, revealing that the octahedral sites have a superior OER catalytic activity, therefore, those are generally considered the active catalytic sites for the OER.^{37,66} The chemistry of the TM in the octahedral site can be tuned by the synthesis conditions and the composition, which provides means to tailor the catalytic activity for the OER.^{67,68} Ni in $Ni_xCo_{3-x}O_4$ can be prepared in the $0 \leq x \leq 1$ range,⁶⁸ whereas $Mn_xCo_{3-x}O_4$ can be obtained as a single phase in the whole $0 \leq x \leq 3$ range.⁶⁷ In both cases, the reorganization of the cation site and their oxidation states leads to substantial modulation of the catalytic activity of the OER.

2.3 TM oxyhydroxides

TM oxyhydroxides formed on the surface of TM have been long recognised as highly active catalytic species for OER in alkaline medium.⁶⁹ Ni oxyhydroxide have received extensive attention because of its particularly high catalytic activity;⁷⁰ however, the observed high performance have been shown to arise from the presence of Fe impurities.^{71,72} In a detailed study, L. Trotochaud

et al. found that the incorporation of Fe impurities in Ni-based OER electrodes leads to the formation of a mixed Ni-Fe layered double hydroxides (NiFe-LDH) with a fougèrite/pyroaurite mineral structure (Fig. 2c), which is responsible of the high catalytic activity.⁷³ In this structure, both Ni and Fe cations reside in octahedral local coordination; however, it was also shown that the long-range order is not important for the high activity of NiFe-LDH. Optimised synthesis of NiFe-LDH electrodes have led to overpotentials as low as 130 mV to achieve a current density of 10 mA cm⁻²,⁷⁴ which has motivated a large number of studies on this type of OER catalysts, in recent years.⁷⁵ The possibility of intercalating the LDH structure increases the flexibility for material design. For instance, the catalytic activity for the OER of NiFe LDHs can be tailored by the intercalation of anions, and it has been shown that the activity of the intercalated NiFe-LDH varies with the redox potential of the anion: low redox potential of hypophosphites favours the catalysis of the OER.⁷⁶ Similar to complex oxides, the substitutional doping of NiFe LDHs is also used for tuning the catalytic activity. For example, V-doping has led to an outstanding catalytic performance due to enhanced conductivity, facile electron transfer, and abundant active sites.⁷⁷ Dionigi and co-workers provided direct evidence that, under applied anodic potentials, NiFe and other Fe-containing LDHs oxidise from as-prepared α -phases to activated γ -phases. The OER-active γ -phases are characterised by about 8% contraction of the lattice spacing and switching of the intercalated ions.⁷⁸

3. OER mechanisms for TM oxide electrocatalysts

Early attempts to describe the OER with parameters that could explain and predict the catalytic activity of TM oxides were based on the bond strength between surface of metal oxides and the adsorbates. Based on kinetic studies, Bockris and Otagawa the concluded that the OER on a series of perovskite oxides, containing metal cations from the first transition row, consisted in the electrochemical adsorption of OH⁻, followed by the rate-determining electrochemical desorption of \cdot OH radical, which

reacts with water to form O₂.^{50,121} The study of adsorbates bonding strengths as descriptors of the OER have been successfully developed with the aid of *ab initio* density functional theory (DFT) calculations, resulting in the elucidation of a well-established adsorbate evolution mechanism (AEM) depicted below in eqn (1)–(4).^{122–125}

Rossmeisl and co-workers investigated trends in the electrocatalytic OER on basis of a database of O*, HO* and HOO* adsorption energies on oxide surfaces, finding that there is a linear scaling relationship between the adsorption energies of the three species.¹²³ In particular, the adsorption energies of HO* and HOO* are closely related because both species bind with the catalyst surface through an oxygen atom with a single bond so that the difference in adsorption energy for these two species ($\Delta G_{\text{HOO}^*}^0 - \Delta G_{\text{HO}^*}^0$) is constant for any catalyst surface (see Fig. 3a).¹²⁶ Thus, the variation in the OER overpotential between different oxide surfaces is determined by the O* adsorption energy. For catalysts that bind oxygen adsorbates strongly to its surface, the formation of the O–O bond in the HOO* adsorbate will be slow, making step 3 (eqn (3)) the rate-determining step (RDS). On the other hand, for catalysts that form labile bonds with oxygen adsorbates the deprotonation of the HO* species will be slow, making step 2 (eqn (2)) the RDS. Another consequence of the fixed adsorption energy difference between adsorbates HO* and HOO* is that the η^{OER} can be described in terms of the formation free energies of O* and HO*, $\Delta G_{\text{O}^*}^0$ and $\Delta G_{\text{HO}^*}^0$, respectively. Plotting η^{OER} vs. ($\Delta G_{\text{O}^*}^0 - \Delta G_{\text{HO}^*}^0$) leads to a general volcano-type relationship independent of the catalysts, as shown in Fig. 3b and c. Therefore, in order to rationalised the OER activity, attention must be focused on the oxygen binding strength on the surface of catalysts

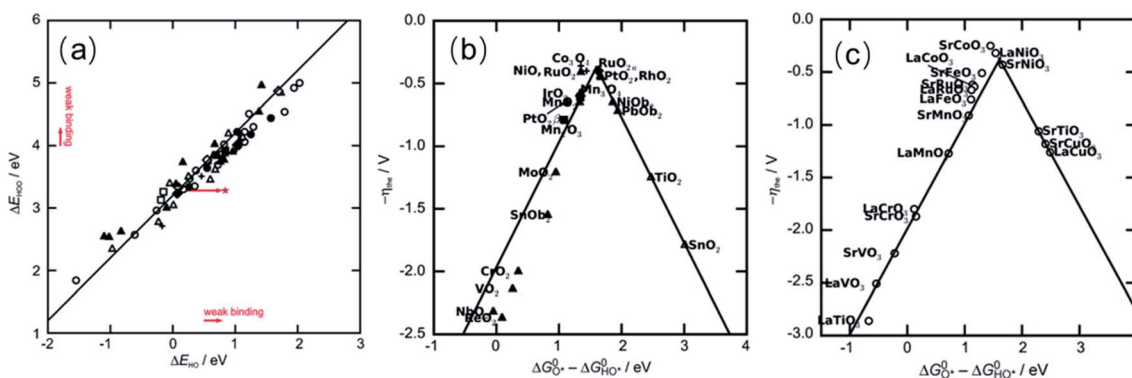

Fig. 3 (a) Adsorption energy of HOO* plotted against the adsorption energy of HO* on perovskite, rutile, anatase, Mn_xO_y, Co₃O₄, and NiO oxides. following the Sabatier principle: the most active catalyst binds oxygen intermediate species to the surface neither too strongly nor too weakly. The most active catalysts are in the centre of this plot and bind these key reaction intermediates neither too strongly nor weakly.

For TM oxides with high covalency in the TM–O bonds, the adsorption energy of oxygen adsorbates generally decreases and the direct O–O bonding with the reversible formation of oxygen vacancy become favourable. In this scenario, a second OER mechanism, the so-called lattice oxygen mechanism (LOM), has been described.^{126,127} Different from the AEM, the LOM proceeds on two neighbouring metal sites, and consists of 4 steps: (1) two HO* on the metal sites undergo deprotonation, resulting in two neighbouring TM–O[−] species, (2) these two oxo species directly couple to form the O–O bond, (3) O₂ is released leaving behind two oxygen vacancies, (4) reoccupation of these vacancies with OH[−]. Fig. 4 shows a graphic comparison of the AEM and the LOM. Since HOO* is not an intermediate in the LOM catalytic cycle, catalysts that drive the OER *via* this mechanism deviate from the trends derived from the AEM which are based on the scaling relation between HO* and HOO*. Over the past few years, the LOM has been confirmed by a series of observations that demonstrate the importance of the bulk oxide electronic structure in the catalytic OER,^{128,129} and direct evidences of involvement of lattice oxygen in the OER.^{130–132}

4. Electronic structure parameters in TM oxides for OER electrochemical activity

From the reaction mechanisms (AEM and LOM) described in the previous section, it is clear that the OER process is driven by (i) *the binding strength of the intermediate oxygen adsorbates (O* and OH*)*, which is important when the AEM operates, and (ii) *the lattice TM–O covalency*, which dictates when the LOM becomes active. Additionally, electrons transfer between the electrolyte and the catalyst's surface will always be involved in the OER, and therefore (iii) *the Schottky barrier* for such electrons transfer,¹³³ is also an important factor the overall OER

process. All of these three factors are derived from the electronic structures of the TM oxides, which provides means to directly correlate measurable and controllable electronic properties with the catalytic activity. On the one hand, the electronic configuration of the TM cations drives the covalency of the TM–oxygen bond in the bulk structure, which is ultimately related to the surface TM binding energies with adsorbate oxide species. A coordination chemistry approach is useful for describing these bonds.⁶¹ The local structure of most TM metal oxides catalytically active for the OER, *e.g.*, perovskite, rutile, spinel and LDH, feature a TM bonded to six O atoms in an octahedral (TM)O₆ coordination. In such coordination, the TM 3d and oxygen 2p atomic orbitals hybridize to form σ orbitals (O 2p with d_{z^2} and $d_{x^2-y^2}$ orbitals of the TM) and π orbitals (O 2p orbitals with d_{xy} , d_{xz} and d_{yz} orbitals of the TM), as depicted in Fig. 5a. The σ and π antibonding (σ^* and π^*) orbitals are named after their symmetry e_g and t_{2g} , respectively, and they are the orbital of interest because their filling determines the covalency of the TM–oxygen bonds. On the other hand, the Schottky barrier for an electron transfer between adsorbates (O* and OH*) and TM oxide catalysts is defined by the energy difference between the unoccupied TM 3d–O 2p band and the redox potential of the electrolyte.

On basis of those factors, several electronic structure descriptors for the OER activity have been recently proposed, addressing the binding strength of adsorbed OER intermediates, the covalency of the TM–O bond, and the energetics for electrons transfer at the interface. The most successful descriptors of the binding strength of adsorbates is the number of electrons in the e_g -orbital of the transition metal cations.⁵¹ As for the TM-covalency, the degree of TM 3d–O 2p hybridization,^{128,129} the energy position of the O 2p band centre,⁵⁹ and the charge-transfer energy, have been used as electronic descriptors.³⁵ Whereas, the Schottky barrier for electrons transfer at the interface has been discussed in terms of the band alignment at the catalysts/electrolyte interface, using parameters like the work function and the electron affinity of the oxide relative to the electrolyte.^{35,63,68} *In the following, we will provide the fundamental basis of these electronic descriptor, and how they are used in order to rationalise OER activity and mechanism. In the following Section 5, we*

characterization. Although the characterisation of the spin configuration is less extended, some authors have specifically studied the magnetic properties and spin configurations of TM oxide OER catalysts using field-cooling magnetization measurements,^{58,137} and superconducting quantum design (SQUID) magnetometer.¹³⁸ From these measurements, an effective magnetic moment μ_{eff} can be calculated, which provides means to determine the average spin configuration. The study of magnetic properties has been particularly extensive in perovskite cobaltite because whether the spin state of Co^{3+} ions at room temperature is a mixture of low spin ($t_{2g}^6e_g^0$) and high spin ($t_{2g}^4e_g^2$) states or an intermediate-spin ($t_{2g}^5e_g^1$) state (see Fig. 5c) has been controversial in the past decades. However, using either interpretation of the spin state in perovskite cobaltite, there is a general agreement that an average e_g occupancy close to the unity is beneficial for the OER activity. Advanced interpretations of the photoelectron spectra and the X-ray adsorption spectra also provide the magnetic properties;¹³⁹ however well-defined samples are usually required.

4.1.1 OER mechanism based on the e_g -orbitals occupancy. The e_g -orbitals occupancy is closely related to the AEM because the binding strength of adsorbate oxygen species depends on the e_g orbitals occupancy. A low occupancy, in the left branch of the volcano plot, favours a strong bond oxygen species so that the formation of the O–O bond in the HOO^* adsorbate (step 3 of the AEM depicted in eqn (3)) is the rate-determining step (RDS). On the other hand, a high occupancy, the right branch of the volcano plot, favours the covalent more labile oxygen bonds that may retard the deprotonation of the HO^* species (step 2 of the AEM depicted in eqn (2)), making it the RDS. According to the e_g filling descriptor, an occupancy close to unity balances the strength of the oxygen adsorbates, efficiently facilitating these RDS, which leads to the highest OER activity.⁵¹ The e_g -occupancy descriptor is based on the AEM ionic model, which is focused on the oxygen binding strength on the surfaces of the catalysts. Consequently, the predicted best OER catalysts are those binding oxygen species not too strong nor too weakly, following the Sabatier principle. However, this descriptor alone fails to explain why, for instance, the catalytic activity of

LaMnO₃ is much lower than those of LaCoO₃ and LaNiO₃, when all these perovskite oxides have the same e_g orbital occupancy ($e_g = 1$). This is a result of the ionic model failing to describe the covalency of the TM–O bond and the participation of lattice oxygen in the catalytic OER, which have been shown to play an important role in highly covalent late TM oxide catalysts.^{130–132}

4.2 Descriptors of the TM–O covalency: degree of TM 3d–O 2p hybridisation

Aiming at a more comprehensive description of the catalytic OER on complex perovskites, Shao-Horn and co-workers introduced a quantitative measure of the TM–O covalency as an additional descriptor for oxides with an e_g -occupancy of 1.⁵¹ They estimated the TM 3d–O 2p hybridisation degree (H) from the background-corrected spectral intensity associated with the O 1s \rightarrow TM 3d–O 2p transition within the O K-edge X-ray absorption (Abs) normalised by the nominal number TM 3d empty levels in e_g (h_{e_g}) and t_{2g} ($h_{t_{2g}}$) symmetries, using the expression: $H = \text{Abs}/(h_{e_g} + \frac{1}{4}h_{t_{2g}})$.^{51,140} H is a measure of the covalency because the O K-edge XAS probes the transition from O 1s to unoccupied states with partial O 2p character hybridised with the valence states of the metal cations, due to dipole selection rules. Fig. 6a shows the potentials to reach 50 $\mu\text{A cm}^{-2}$ current density as a function of the H for LaMnO₃, LaCoO₃ and LaNiO₃. The linear decrease of the overpotentials with the increase of the TM–O covalency led the authors to conclude that a greater covalency between the TM and the oxygen, where the active redox couple of the TM cation has a larger O 2p character, promotes the charge transfer between surface cations and adsorbates, therefore accelerating the rate-determining steps in the OER.

Suntivich and co-workers estimated empirical trends of the TM 3d–O 2p hybridisation in complex perovskite using the pre-edge feature of the O K-edge X-ray absorption spectrum.¹⁴¹ The authors found that the hybridisation increases with the number of 3d electrons, which is consistent with the expected electronegativity trend, and also with the oxidation state of the TM cation. It was recognised that a higher oxidation state of the TM in the oxide reduces the energy difference between the TM 3d and the O 2p, leading to an increased covalency.^{141,142}

In 2013, Shao-Horn and co-workers demonstrated that the energy level of the O 2p band relative to the Fermi level (E_F) could be also used as a descriptor for the TM–O covalency and activity of complex perovskite catalysts for the OER, as well as their stability.⁵⁹ Fig. 6b shows how the shift of the O 2p band centre closer to the E_F in a series of perovskite cobaltite, correlates with the decrease of the overpotential needed to reach a 0.5 mA cm^{-2} . However, they found a shift limit from which the materials undergo amorphization during the OER, which leads to instability and activity losses. These observations suggested the participation of lattice oxygen in the reaction, which has been later confirmed for a series of perovskite cobaltite.¹³⁰ Although the level of the O 2p band relative to the E_F provides satisfying description of the OER on highly conducting oxides, is less reliable to describe OER kinetics on semiconductors and insulating oxides because the Fermi level may lie in forbidden energies and can be poorly defined for this type of materials.

More recently, Hong and co-workers made use of a combination of X-ray emission, X-ray absorption, and X-ray photoelectron spectroscopies to examine the electronic structure of a series of complex perovskite oxides LaBO₃ (B = Cr, Mn, Fe, Co and Ni).¹⁴³ These studies allowed the direct determination of the energy difference between the TM 3d and the O 2p, the so-called charge transfer energy (Δ), which can be directly related with the TM 3d–O 2p hybridisation degree, and therefore with the covalency in the TM–O bonds. The group of authors later reported that reducing Δ greatly enhance the OER activity of oxides (Fig. 6c), and the trend across 10 oxides was statistically stronger than using the O 2p-band centre as the descriptor for both semi-metallic and semi-conducting oxides.³⁵ They showed that the charge-transfer energy, determined from the experimental elucidation of the band positions, can be used to evaluate trends in the electronic and chemical interactions at the oxide/electrolyte interface relevant to the OER, specifically the electron-transfer kinetics (electrochemical steps) and hydroxide affinity (chemical steps). As a result, the analysis of the charge-transfer energy of catalytic metal oxides can explain not only OER activities trends but also changes in the mechanisms of the OER from electron-transfer-limited to proton-electron-coupled, to proton-transfer-limited reactions.

4.2.1 OER mechanism based on the degree of TM 3d–O 2p hybridisation. On basis of the AEM, the enhanced OER activity observed upon increasing the covalent mixing in the TM–O bond at a constant e_g filling (Fig. 6a) was suggested to derive from a larger O 2p character of the active redox couple of the TM ion, which promotes the charge transfer between surface cations and key adsorbates, improving therefore the OER activity.⁵¹ The beneficial effect of a high TM–O covalency on the OER catalytic activity have been shown to come together with substantial surface amorphization of the samples under the OER process,^{59,132,144} even reaching an upper limit from which further increases in covalency lead to bulk amorphization and partial deactivation of the catalysts.⁵⁹ Such changes in surface morphology highlights the role of the TM–O covalency in the participation of lattice oxygen in the catalytic OER, which have been rationalised on basis of different electronic descriptors of the OER. As the TM–O covalency increases, for instance as x increases from 0 to 1 in systems like $\text{Sr}_x\text{La}_{1-x}\text{CoO}_3$ or $\text{Sr}_x\text{La}_{1-x}\text{FeO}_3$, the Fermi level moves closer to the O 2p band centre (Fig. 7). As the Fermi level moves down in energy and closer to the O 2p states of the oxide, the antibonding TM 3d states below the Fermi level exhibit greater oxygen character, *i.e.*, there is a greater covalency of the metal–oxygen bond. The oxidation of lattice oxygen in the perovskites becomes thermodynamically favourable when O 2p states at the perovskite Fermi level lie above the redox energy of the $\text{O}_2/\text{H}_2\text{O}$ couple, as shown in Fig. 7, triggering therefore the LOM.¹²⁷ Using *in situ* ^{18}O isotope labelling mass spectrometry, Grimaud and co-workers provided direct experimental evidence that the O_2 generated during the OER on some highly active oxides can come from lattice oxygen.¹³⁰ Density functional theory was employed by Yoo and co-workers to investigate the electronic origin and feasibility of the LOM on perovskites, finding that the different thermodynamic driving forces of lattice oxygen participation on $\text{LaMO}_{3-\delta}$ ($M = \text{Ni}, \text{Co}, \text{and Cu}$) are explained by the changes in the oxidation state of the TM site throughout the reaction.¹⁴⁵ Further DFT studies by this group of authors suggested that the LOM can lead to higher OER activity than the AEM by minimizing the thermodynamically required overpotential. Interestingly, they showed that whereas the OER activity volcano for the AEM is universal for all perovskites, that for the LOM depends on the identity of the A cation in ABO_3 .¹⁴⁶

In situ ^{18}O isotope labelling mass spectrometry has been also employed to provide evidences of the LOM in oxides other than covalent perovskites. Amin and co-workers used isotope labelling together with differential electrochemical mass spectrometry to study the OER mechanism on spinel Co_3O_4 .^{147,148} Their work showed that the alkaline OER in H_2 ^{18}O -containing electrolyte generated an amount of $^{18}\text{O}^{16}\text{O}$ evolved increases from cycle to cycle before reaching a steady-state value, showing that a surface layer of Co_3O_4 was taking part in OER *via* an oxygen exchange mechanism. They found that total number of oxygen atoms of the oxide participating in OER was 0.1 to 0.2% of the total oxide loading, corresponding to about 10–30% of the surface atoms, which represented the catalytically active sites.¹⁴⁷

Although the LOM is associated with highly active covalent oxides, the OER mechanism for NiFe oxyhydroxides, the most

active OER catalyst in alkaline OER, has been shown not to proceed *via* lattice oxygen exchange.^{149,150} Roy and co-workers used a model system of mass-selected NiFe nanoparticles and isotope labelling experiments to show that oxygen evolution in 1 M KOH does not proceed *via* lattice exchange on very highly active electrodes.¹⁵⁰ The lack of lattice oxygen participation in the OER on NiFe oxyhydroxides was further confirmed by Lee and co-workers in a mechanistic study based on ^{18}O -labelling experiments in combination with *in situ* Raman.¹⁵¹ However, in the same study, they also found that lattice oxygen does participate in the OER on Fe-free Ni and NiCo oxyhydroxides catalysts, specifically in the formation of a NiOO^- species that was identified as an OER intermediate. Based on DFT calculation, Huang and co-workers proposed that the OER proceeds *via* the LOM pathway on the metal oxyhydroxides only if two neighbouring oxidized oxygens can hybridize their oxygen holes without sacrificing metal–oxygen hybridization significantly, finding that the LOM is highly favoured in the OER on $\text{Zn}_{0.2}\text{Co}_{0.8}\text{OOH}$.¹⁵²

4.3 Descriptor of the Schottky barrier for e^- transfer: band alignment at the catalysts/electrolyte interface

As described in above in Section 4.2, the band energy position in metal oxides dictates the charge transfer energy, which is a measure of the covalency of the TM–O bond. Additionally, the band positions relative to the redox potential of the OER provides information on the electronic and chemical interaction at the catalysts/electrolyte interface relevant to the OER.³⁵ On the one hand, the energy difference between the unoccupied TM 3d–O 2p band and the OER redox potential defines the electron affinity of the oxide relative to the electrolyte, and it represents a Schottky barrier for electron transfer, as schematically shown in Fig. 8a. On the other hand, the energy difference between the potential of the electrolyte and the Fermi level is a measure of the hydroxide affinity of the catalyst (see Fig. 8a). In a comparative study of several oxides, Hong and co-workers found that oxides with a larger charge-transfer energy have a higher Schottky barrier for electron transfer at the oxide–electrolyte interface (Fig. 8b).³⁵ As the charge transfer energy decreases in the series of oxide catalysts, the barrier for electron transfer associated with OER decreases. Additionally, upon decreasing the charge transfer energy, the electrical conductivity of the oxides tends to increase, which brings about an extra benefit of a low resistance to the current flow during the OER.¹⁵³ However, the intrinsic OER active is more influenced by the presence of low-energy TM 3d orbital states that facilitates the interface electron transfer associated with the OER process. Yun and co-workers recently found that semiconducting LaCoO_3 has an intrinsic OER activity more than one order of magnitude higher than that of metallic LaNiO_3 , in contrast to previous reports.¹⁵⁴ The group of authors showed that misleading interpretations could be avoided by using very thin films of the catalyst on conducting interlayer as samples.

We have been recently working on a systematic approach to study the relationship between the OER catalytic activity and the electronic structure of complex perovskite, double perovskite and spinel systems such as $\text{Sr}_x\text{La}_{1-x}\text{FeO}_3$, $\text{La}_{2-x}\text{Sr}_x\text{NiMnO}_6$ and $\text{Ni}_x\text{Co}_{3-x}\text{O}_4$.^{63,68,98} For all three systems, increasing x in the

range $0 \leq x \leq 1$ triggers a shift of the Fermi level (E_F) closer to the valence band maximum (VBM) and induces the formation of hole states (unoccupied) below the conduction band minimum (CBM), near the E_F . We argue that *filled* electronic states (*i.e.*, VBM) near the E_F improve the orbital overlap with key intermediates, favouring their formation (Fig. 8d). At the same time, unoccupied states close to the E_F increase the electron affinity of the oxide semiconductors, thereby facilitating charge transfer at the interface associated with water oxidation. We found linear correlations between the OER activity and the downshift of the E_F , as well as with the hole state density, which shows that band energy level descriptors can be very powerful to describe the OER activity of TM oxides.

5. Material engineering strategies for the OER tailoring based on electronic parameters

As described above, in Section 4, many efforts have been devoted to discovering the correlation between the electronic structure and OER catalytic activity of TM oxide catalysts. Several electronic structure descriptors of important parameters for the OER catalysis, such as the adsorption energy of adsorbates (described by the e_g occupancy), the covalency (described by O 2p energy level and charge transfer energy) and the interface energetics (ionisation potential, E_F and electron

affinity), have been developed. In this section, we will focus on strategies to modify those electronic parameters that determine the OER catalytic properties of TM oxides through intentional doping, strain and defect engineering.^{155,156}

5.1 Doping

Doping is a common and efficient strategy to tuning the electronic structure of TM oxide catalysts, due to the high flexibility in compositions and crystal structures. Introducing or substituting foreign metal ions with different radius size,

valence state and electron-donating ability may enable charge transfer occurred through shared oxygen ions or change the lattice parameters and thus the degree of overlap between atomic orbitals, finally altering the electronic, optical and magnetic properties of the oxides as well as their catalytic activity.

Various cases of metal doping have been reported to successfully improve the catalytic activities compared with the pristine metal oxide catalysts due to advantageous modification of electronic structure.¹⁵⁷ Interestingly, among these cases, the

incorporation of Fe can significantly enhance the OER catalytic activities of Co¹⁵⁸ or Ni (oxy)-hydroxides.⁷³ The catalytic activity of Ni_xFe_{1-x}OOH even reached 1000-fold higher than the pristine NiOOH.²⁰ Nowadays, layer-structured Ni_xFe_{1-x}OOH electrocatalysts show the best OER catalytic activity in alkaline condition. However, although the superior performance of Ni_xFe_{1-x}OOH has been well accepted, there still remains a confusion how iron dopants influence the OER activity. In the 1980s, Corrigan⁷¹ found the crucial effect of Fe impurities on the improvement of the catalytic activity, which has been later verified by Trotochaud and co-workers⁷³ in comparative experiments using an increasing Fe concentration in the KOH solution for the electrochemical tests. The group of authors argued that the incorporation of Fe promoted the electronic conductivity of NiOOH. As illustrated in Fig. 9a, the results of electrochemical investigation revealed that the Ni redox peaks of Ni_xFe_{1-x}OOH catalysts shift toward the anodic direction with increasing *x*, suggesting the changes happened on the electronic structure.^{44,159,160} Similar findings were also obtained from electrochemical testing of Fe-doped CoOOH;¹⁵⁸ it seemed that Fe incorporation had a similar influence on Ni and Co hosts. To further uncover the effect of Fe in Ni_xFe_{1-x}OOH, Friebel and co-workers used operando X-ray absorption spectroscopy (XAS) to reveal that Fe³⁺ in Ni_xFe_{1-x}OOH occupies octahedral sites with unusually short Fe–O bond distances induced by edge-sharing with surrounding [NiO₆] octahedra and they also identified that Fe cations were the active sites

instead of Ni cations by computational results.⁴⁰ In addition, Ahn and Bard utilized surface interrogation scanning electrochemical microscopy (SI-SECM) technology to directly investigate the OER kinetics of Ni⁴⁺ and Fe⁴⁺ in Ni(OH)₂, FeOOH, and Ni_xFe_{1-x}OOH and they claimed that the OER kinetics were much more fast on iron sites. These results seem to indicate that Fe dopants are the active sites.¹⁶¹ In order to more directly identify the existence of Fe species in Ni_xFe_{1-x}OOH, Mössbauer spectroscopy, has been applied in the investigation of Ni_xFe_{1-x}OOH electrocatalysts.¹⁶² For example, Jamie and co-workers reported the first direct evidence for the formation of Fe⁴⁺ in NiFe oxide through operando Mössbauer spectroscopy.¹⁶³ However, they proposed that the detected Fe⁴⁺ species did not directly serve as the active site in the OER process, although their existence had great effect on the improvement of OER activity for NiFe oxide electrocatalyst. Using *in situ* differential electrochemical mass spectrometry (DEMS) and XAS, Görlin *et al.*¹⁶⁴ found that Ni ions remained in the Ni²⁺ state with the iron incorporation which might be responsible for the enhanced faradaic efficiency, while the Ni ions in pure NiOOH would be oxidized from Ni²⁺ to Ni³⁺ or Ni⁴⁺ during OER process, leading to a lower faradaic efficiency (Fig. 9b and c). However, later, Nocera *et al.* proposed that the incorporation of Fe could promote the formation of Ni⁴⁺ *via* the Lewis acid effect, causing the observed improved OER performance.¹⁶⁵ More recently, Xu and co-workers explained the effect of iron of Ni_xFe_{1-x}OOH on the OER process from a perspective of the local spin

configurations of surface iron and nickel.¹⁶⁶ As shown in Fig. 9d, the electronic configuration of surface Fe³⁺ cations under the stable high spin state have 5 unpaired electrons (1 per d orbital), while the low spin state of surface Ni³⁺ only possesses one single

electron at e_g orbitals; a spin channel around the Fe sites can be obviously observed in Fig. 9e. During the OER process, the possible orbital interactions between Fe³⁺/Ni³⁺ and the *OH, *O, and *OOH species are shown in Fig. 9f. The group of

authors found that the different d-orbital occupations of Fe^{3+} and Ni^{3+} could result in distinct reaction kinetics, and that iron sites in $\text{Ni}_x\text{Fe}_{1-x}\text{OOH}$ could promote the OER process through both the reactant adsorption and product desorption. Actually, other metal cations such as La, Y, Cd, Ce, Cr, and Zn *etc.*, also have been reported to be dopants incorporated in layered metal hydroxides, but their improvement on the OER performance has been less pronounced compared to Fe.^{167–170}

A typical group of metal oxides featured by the highly compositional and structural flexibility with the unit formula of ABO_3 , where A usually is the larger ions such as rare-earth metal cations and alkali-earth metal and B is the smaller ions such transition metal cations, is the perovskite-type metal oxides. The ABO_3 structure of perovskite can greatly adapt cation incorporation through partially substituting the A or B cation or both of them with other metals giving the $(\text{A}_x\text{A}'_{1-x})\text{BO}_3$, $\text{A}(\text{B}_y\text{B}'_{1-y})\text{O}_3$, $(\text{A}_x\text{A}'_{1-x})(\text{B}_y\text{B}'_{1-y})\text{O}_3$ or even more complex compositions. In the periodic table, over 90% of the metal elements could be potentially used to construct perovskite oxides, which provides a broad diversity and possibility for doping.¹⁷¹ Depending on the adjustment of doping, perovskite oxides not only offer controllable electronic structure for modifying the OER activities but they also provide excellent models for establishing correlations between the activity and the electronic properties of surface and/or bulk properties *via* establishing electronic descriptors. For example, Xie and co-workers have reported that the Yb doped CaMnO_3

electrocatalyst showed a significant enhancement of the OER performance compared with pure CaMnO_3 , which could be ascribed to optimized electron occupation numbers of e_g orbital by doping.¹⁷² Zhao and co-workers also found that the co-doping of Sr and Fe into $\text{PrBaCo}_2\text{O}_{5+\sigma}$ perovskites led to a favourable e_g electron filling, which could improve the intrinsic OER activity.¹⁰⁹ Mefford and co-workers synthesized a series of $\text{La}_{1-x}\text{Sr}_x\text{CoO}_{3-\delta}$ perovskites with the different amount of Sr dopants. They claimed that the covalency of the Co–O bond can be enhanced through Sr incorporation and thus influence the OER activities.³⁶ Similarly, Xu and co-workers introduced Fe dopants into LaCoO_3 for modifying its OER activity,¹³⁸ and they showed by means of DFT calculation that the increased performance relates to an enlarged covalency of Co–O with 10% incorporation of Fe in LaCoO_3 . On the other hand, Liu and co-workers analysed the effect of Sr doping in the LaNiO_3 on the improvement of OER activity, and they rationalised the observed results based on the analysis of energy levels derived from X-ray photoemission spectroscopy (XPS) and X-ray absorption spectroscopy (XAS) in combination with DFT calculation.¹⁷³ As is shown in Fig. 10a–c, the results indicated that an up-shift energy of the O 2p band relative to the Fermi level occurred with rising x in $\text{La}_{1-x}\text{Sr}_x\text{NiO}_3$, which strengthened the degree of Ni 3d–O 2p hybridization and reduced the charge transfer energy, which resulted in a significant enhancement the OER activity. IN a similar analysis approach, Zhang and co-workers recently tuned the electronic structure of

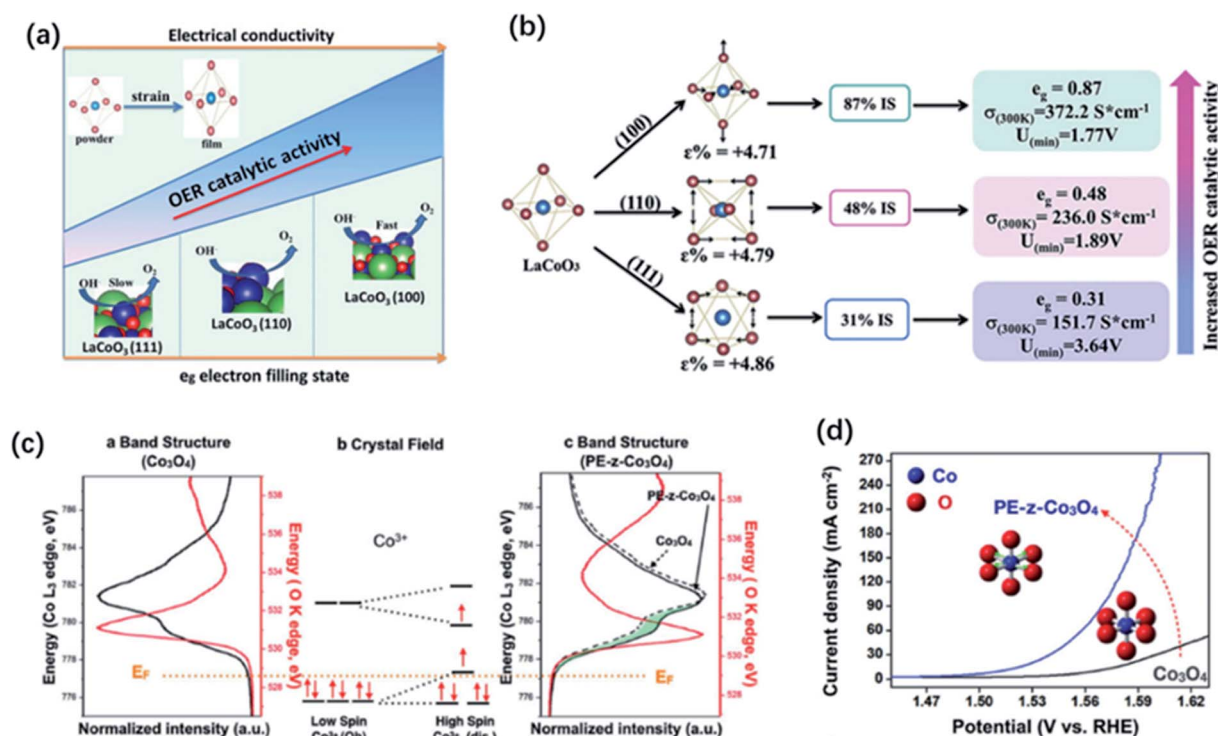

Fig. 12 (a) Spin-state regulation by lattice-oriented control of LaCoO_3 epitaxial films. double perovskite $\text{La}_2\text{NiMnO}_6$ by Sr doping, which effectively led to higher OER activities of $\text{La}_{2-x}\text{Sr}_x\text{NiMnO}_6$.⁹⁸ Their investigation on electronic structures discovered that the Sr doping induced Ni^{3+} states, resulting in the upshifted valence band centre and enhanced the hybridization of O 2p with Ni 3d and Mn 3d orbitals (Fig. 10d and e). Besides, the increased hole states originated from Ni^{3+} states decreased the energy barrier of the electron transfer from 0.44 to 0.12 eV. They claimed that the enhanced hybridization of O 2p with Ni and Mn 3d orbitals and the increased hole states should be responsible for the better OER activities.

Another group of metal oxides characterized by controllable composition and electron structure is the spinel family. In the typical structure of spinel oxides, there exist two geometric sites including tetrahedral (Td) sites which are normally half occupied by metal cations and octahedral (Oh) sites of which only one-eighth are filled by metal cations. The unoccupied geometric sites enable spinel-type oxides to largely accommodate the migration of metal ions. Otherwise, two geometric TM cations possess different coordination environment and they would compete for overlapping with the neighbouring oxygen because four neighbouring metal cations (three are in octahedral sites and the other one is in the tetrahedral sites) shared one common oxygen atom. Thus, the electronic properties of the metal cations in both sites and the oxygen anions closely correlate with each other. Doping or substituting other metal ions into Oh or Td sites becomes an effective approach to tuning the electronic structure of spinel oxides and influences their OER performance. For example, Zn, Ni, Cu, and Fe dopants introduced into Co_3O_4 spinel have been widely reported and their effects on the electronic structure and catalytic properties have been deeply investigated.^{37,170,174,175} Driess and co-workers found that the OER activity of ZnCo_2O_4 electrocatalyst was slightly better than Co_3O_4 in alkaline electrolyte, which could be ascribed to more accessible Co^{3+} in octahedral sites of ZnCo_2O_4 surface owing to the preferential loss of Zn ions under reaction conditions.³⁷ Tan and co-workers synthesized different metal incorporated spinel catalysts MCo_2O_4 ($\text{M} = \text{Ni}, \text{Zn}, \text{Mn}, \text{etc.}$) and they uncovered that ZnCo_2O_4 with a normal spinel structure where all the Co cations were in octahedral sites exhibited the better OER activity.¹⁷⁶ The degree of M–O covalency, as measured by the hybridization of M d and O 2p states, is also applied to connect the effect of doping with OER catalytic properties in spinel. Xu co-workers conducted an investigation on linking the Co–O covalency with the OER activity of Fe incorporated $\text{ZnFe}_x\text{Co}_{2-x}\text{O}_4$ spinel catalyst.¹²⁹ The results showed that 10–30 at% Fe doping was beneficial to promote the injection/extraction of electrons from oxygen and lead to an enhanced covalency between Co 3d and O 2p, which is responsible for the improvement of the OER performance (Fig. 11a and b). Later, the same group reported that the OER activity followed the trend of $\text{Co}_3\text{O}_4 > \text{ZnCo}_2\text{O}_4 > \text{AlCo}_2\text{O}_4$, indicating that the octahedral CoO_6 block dominated the OER activity, and explained the higher catalytic activities of the octahedral metal cations than the tetrahedral ones by the concept of covalency.¹⁷⁷ They also observed a greatly improved OER performance by the doping of Li and Fe into ZnCo_2O_4 ,

obtaining a highly active $\text{Li}_{0.5}\text{Zn}_{0.5}\text{Fe}_{0.125}\text{Co}_{1.875}\text{O}_4$ catalysts. They proposed that the enhanced OER performance was attributed to the charge shift from the oxygen to metal cations in octahedral sites *via* Li doping and enlarged covalency of $\text{Co}_{\text{Oh}}\text{–O}$ bond *via* Fe doping (Fig. 11c and d). Additionally, Zhang and co-workers introduced Ni into Co_3O_4 and conducted a systematic investigation on the influence of Ni dopants on the electronic structures of $\text{Ni}_x\text{Co}_{3-x}\text{O}_4$.⁶⁸ Using XPS and XAS, they found that the incorporation of Ni in the trivalent oxidation state induces the generation of an unoccupied hole state, which could decrease the energy barriers of electron transfer for a faster kinetics. Results also showed that there is a shift of the VBM by 0.27 eV closer to the E_F and enhanced the hybridization of O 2p with Ni 3d and Co 3d orbitals, which promoted the adsorption of OH intermediates on the surface of $\text{Ni}_x\text{Co}_{3-x}\text{O}_4$ for a better OER activity than Co_3O_4 (Fig. 11e and f).

In addition to the examples mentioned above, other studies on tuning the electronic structure and improving the OER activity of metal oxides by doping have also been reported. For instance, Zhang and co-workers modified the electronic properties of NiO through Li doping ($\text{Li}_x\text{Ni}_{1-x}\text{O}$) to improve the performance toward OER.¹⁰³ According to their results, the significantly improved OER activities of $\text{Li}_x\text{Ni}_{1-x}\text{O}$ could be ascribed to the generation of hole states at 1.1 eV above the Fermi level and the enlarged hybridization degree of O 2p–Ni 3d by Li doping which in turn resulted in the optimal adsorption strength of OH intermediates. Patzke *et al.* improved the OER activity of $\alpha\text{-Mn}_2\text{O}_3$ through Mo doping.¹⁷⁸ According to their findings, Mn_2O_3 with 2.64% Mo dopants exhibited the best OER activity. They claimed that the doping of Mo into the $\alpha\text{-Mn}_2\text{O}_3$ lattice along with the structural distortion had great influence on improving the OER activity of pure $\alpha\text{-Mn}_2\text{O}_3$. Previous research showed that the energy of $\text{Ni}^{\text{IV}}/\text{Ni}^{\text{III}}$ redox pair located at the top of the O-2p bands resulted in a strong bonding strength between the adsorbates on the surface and $\text{Ni}^{\text{IV}}/\text{Ni}^{\text{III}}$ redox cation, which was an important premise for high OER activity. However, stoichiometric LiNiO_2 with well-ordered Li^+ and Ni^{III} is difficult to be obtained due to the generation of Ni^{II} . Based on these, Gupta and co-workers successfully prepared Al doped LiNiO_2 catalysts ($\text{Li}_{1-x}\text{Ni}_{1+x}\text{O}_2$) with better ordered lattice structure *via* solution combustion method at low temperature.¹⁷⁹ They proposed that Al dopants could stabilize Ni^{III} with higher concentration for the better OER activity.

5.2 Strain engineering

The compositional flexibility of metal oxides could provide convenience to modulate the electronic structure for a better OER activity, present advanced thin-film deposition techniques also offer the great opportunities to tune the properties of functional metal oxides through strain engineering. The physical and chemical properties of thin film and nanostructured metal oxides may largely differ from their bulk or powder form, which results in extra degrees of freedom for the modification by strain engineering. The modulation of electronic structure through strain effects can change a number of electronic structure parameters such as the metal d-band and oxygen 2p-

band centres and e_g occupancy *etc.* In the spinel and perovskite oxides, strain can lead to the distortion of metal–oxygen octahedra from the ideal cubic symmetry. The degeneracy of e_g orbitals can be changed through enlarging the electron filling in the $d_{x^2-y^2}$ orbital caused by tensile strain and in the d_{z^2} orbital caused by compressive strain. Owing to the alteration in orbital overlap, the metal d-band and oxygen 2p-band centers as well as the binding strength of the adsorbed intermediates can be changed. For example, Petrie and co-workers observed the improvement of the OER activity on compressively strained LaNiO_3 thin film in comparison with their unstrained state.¹⁸⁰ They proposed that compressive strain could cause orbital asymmetry and induce splitting of the e_g orbitals which result in the higher occupancy of the out-of-plane d_{z^2} orbitals. The extra occupancy of the d_{z^2} orbitals reduces the binding strength between the metal cation and adsorbate intermediates, resulting in better activity for OER and ORR.

Recently, much attention has focused on the strain engineering of LaCoO_3 perovskite to modify its electronic structure, due to unique nature that the electron configuration of Co^{3+} that can thermally transit from low spin (LS: $t_{2g}^6 e_g^0$) to higher spin state with the e_g orbital configuration of $e_g^{\sim 1.0}$ at room temperature. By decreasing the particle size of LaCoO_3 to 80 nm, Zeng *et al.* observed the spin-state transition of Co ions from low-spin to high-spin states and the increase of e_g filling from unity to close to the favourable electron number of 1.2. Thus, LaCoO_3 catalysts with the particle size of 80 nm displayed a better OER activity than that of other larger sized samples and the bulk.⁵⁷ Similarly, through strain engineering, Xie and co-workers prepared three kinds of epitaxially strained thin films of LaCoO_3 perovskite with (100), (110), and (111) lattice orientation, respectively.⁵⁸ The LaCoO_3 films with different lattice orientations exhibited different distortion degree of the CoO_6 octahedron, causing a spin-state transition occurred on cobalt from a low spin state (LS $t_{2g}^6 e_g^0$) to an intermediate spin state (IS $t_{2g}^5 e_g^1$). As a result, LaCoO_3 films with (100) orientation showed the best OER performance duo to its favourable e_g electron number of 0.87 and higher electrical conductivity (Fig. 12a and b). Modulating the spin state of cobalt by strain control was also reported by Hsu and co-workers.¹⁸¹ They found that enlarging

the lattice constant on the Co_3O_4 surface could change the spin state of surface Co^{3+} cations from t_{2g}^6 to the high spin state of $t_{2g}^4 e_g^2$, which remarkably enhanced the overlap of the e_g orbital of cobalt with the oxygen adsorbates, and thereby improving the OER performance (Fig. 12c and d).¹⁸¹

Strain could also enhance the formation of oxygen vacancy to modify the OER activity of metal oxide catalysts. For $\text{SrCoO}_{3-\delta}$ thin films, tensile strain would upshift the O 2p-band relative to the Fermi level and it is beneficial for the formation of oxygen vacancy manifesting as the reduction of a small amount of Co^{4+} to Co^{3+} . Lee *et al.* reported that the oxygen deficiencies of $\text{SrCoO}_{3-\delta}$ thin films can be tailored from $\delta \leq 0.1$ to $\delta \sim 0.25$ through epitaxial strain engineering.¹⁸² The changes in the oxygen content happened on the modest amounts of tensile strain over 1%. The electrochemical measurement showed the improved OER activities of tensile-stained $\text{SrCoO}_{3-\delta}$ thin films with an increased degree of strain. The authors ascribed the enhancement of OER activity to the existence of oxygen vacancies or the increase of Co^{3+} caused by strain. Otherwise, Du *et al.* also confirmed the effect of strain on oxygen vacancy formation.¹⁸³ They grew the tensile strained NdNiO_3 thin films on SrTiO_3 substrates and found that enhancing tensile strain would generate a higher content of oxygen vacancies in NdNiO_3 . They claimed that when the effect of oxygen vacancies could be negligible, the tensile strain was not good for the OER process while compressive strain was beneficial for that due to the strain-induced orbital splitting for a higher filling of the $d_{3z^2-r^2}$ orbital and resultant weaker Ni–O binding strength. Nevertheless, when the tensile strain was large enough to enhance the formation of oxygen vacancies, an improvement of the OER performance could be seen. The improved performance was associated with an e_g orbitals occupancy slightly larger than 1 due to the partial reduction of Ni^{3+} to Ni^{2+} caused by the oxygen vacancy formation.

5.3 Defect engineering

The structural and compositional flexibility of metal oxides also involve high tolerance in element defects, including metal cations and oxygen vacancies.^{184,185} Defects can greatly influence the electron and orbital distribution of metal oxides. Thereby,

Fig. 13 (a) and (b) Differential charge density upon the creation of oxygen vacancies and a slice along the (100) plane. (c) $d_{3z^2-r^2}$ and $d_{x^2-y^2}$ contributions of the Co ions in a pristine bulk system and the Co ions surrounding oxygen vacancies. Reproduced with permission.¹⁸⁹ Copyright 2016, American Chemical Society.

defect engineering is an effective strategy to modify the electronic structure and catalytic properties of metal oxide electrocatalysts. For example, Wang *et al.* produced Sn vacancies on the surface of SnCoFe perovskite hydroxide ($\text{SnCo}_{0.9}\text{Fe}_{0.1}(\text{OH})_6$) by energetic Ar plasma treatment.⁹⁰ The generated Sn vacancies reduced the coordination numbers of the neighbouring active sites, which promoted reactant adsorption and charge transfer. And the Sn vacancies also promoted exposure of active Co and Fe sites, tuned conductivity and adsorption energy of the intermediates, thus significantly improving the OER performance. Zhu and co-workers reported the introduction of A-site cation defects in $\text{La}_{1-x}\text{FeO}_{3-\delta}$, which lead to the formation of highly oxidative oxygen species ($\text{O}_2^{2-}/\text{O}^-$) and Fe^{4+} species.¹⁵⁶ They proposed that the $\text{O}_2^{2-}/\text{O}^-$ species might be the active sites for OER and Fe^{4+} species with an optimal e_g orbital filling ($t_{2g}^3e_g^1$) also promoted the OER processes.

Actually, generating oxygen vacancies is easier compared to metal cation vacancies owing to the low formation energy of oxygen vacancies and they usually have a direct influence on the M–O bonds.¹⁸⁶ Therefore, many studies focused on the introduction of oxygen vacancies in metal oxides to tune their electronic structure and improve the OER performance. Wang *et al.* reported that the introduced oxygen vacancies in Zn-doped CoOOH would cause the transformation of the regular CoO_6 octahedron to an elongated or compressed CoO_6 octahedron (Jahn–Teller distortion), which enhance the lift degeneracy of the t_{2g} and e_g orbitals.¹⁸⁵ The electron configuration of Co^{3+} ($t_{2g}^6e_g^0$) transferred to a more optimized e_g state filling ($t_{2g}^5e_g^1$), which could facilitate bonding with intermediates due to the stronger overlap of σ -bonding e_g with O-2p than π -bonding t_{2g} orbital and finally promote the OER activity. Kim and co-workers prepared the oxygen deficient perovskite $\text{Ca}_2\text{Mn}_2\text{O}_5$ with a higher OER mass activity of 30.1 A g^{-1} at 1.70 V (vs. RHE) in comparison to the perovskite CaMnO_3 .¹⁸⁷ They claimed that the unit cells of $\text{Ca}_2\text{Mn}_2\text{O}_5$ were elongated in *b*- and *c*-directions owing to the existence of oxygen vacancies and the electronic configuration of Mn^{4+} ($3d^3$) with t_{2g}^3 was optimized to $t_{2g}^3e_g^1$ of Mn^{3+} ($3d^4$), which both were favorable for the adsorption of OH intermediates, thereby exhibiting higher OER activity. Moreover, Mefford *et al.* found that the increase of Sr substitution in $\text{La}_{1-x}\text{Sr}_x\text{CoO}_{3-\delta}$ resulted in more oxygen vacancies, stronger covalency of the Co–O bond, which led to better OER performance.³⁶

Zhu and co-workers found that controlling oxygen defects in $\text{PrBa}_{0.5}\text{Sr}_{0.5}\text{Co}_{1.5}\text{Fe}_{0.5}\text{O}_{5+\delta}$ (PBSCF) could obviously promote the OER kinetics.¹⁸⁸ Using surface-sensitive characterization and DFT calculations, they proved that excessive oxygen vacancies enhanced OH^- affinity and lowered the theoretical formation energy of O^* intermediates on the surface, thereby significantly improving the OER activity. But they also proposed that excessive oxygen vacancies may lead to larger energy band gap and lower O 2p band position relative to the Fermi level of $\text{PrBa}_{0.5}\text{Sr}_{0.5}\text{Co}_{1.5}\text{Fe}_{0.5}\text{O}_{5+\delta}$, which may be not beneficial for OER process. Through DFT calculations, Tahini and co-workers found that the introduction of oxygen vacancies in SrCoO_3 would lead to a local distortion of the Co–O bonds and donate its electrons to neighbouring Co cations.¹⁸⁹ The reduced Co sites

on the surface and Co–O bonds in the bulk lead to a reduction in the overlap between the Co 3d and O 2p orbitals, thereby resulting in the decrease of the electron transfer between the catalyst and the reactant intermediates (Fig. 13a–c). In addition, Miao *et al.*¹⁹⁰ and Liu *et al.*¹⁹¹ also found that OER activities of $\text{PrBaCo}_2\text{O}_{6-\delta}$ and $\text{La}_{0.7}\text{Sr}_{0.3}\text{CoO}_{3-\delta}$, respectively, decreased after introducing oxygen vacancies. Thus, optimizing OER performance by properly introducing oxygen vacancies is very important.

6. Summary and perspectives

Improving the kinetics of the OER with low-cost TM oxide catalysts is one of the big challenges of the scientific and engineering communities owing to the important role of the electrochemical water splitting in the introduction of renewable sources in any future energy scenario. In this article, we reviewed studies of the electronic structure of the TM oxide catalysts for the OER and the design of materials with high catalytic performances on basis of such electronic properties. The identification of electronic structure parameters associated with (i) the adsorbate binding strength, (ii) the covalency of the TM–O bonds, and (iii) the interface energetics can provide rational bases to explain the influence of the composition on the OER catalytic activity and guidelines for the formulation of new catalyst with improved activity. A key observation in the current literature is that highly covalent oxides tend to have higher catalytic activities, triggering a mechanism in which the lattice oxygen has been shown to participate. This has brought the spotlight on the activation of lattice oxygen as a way to improve the OER catalytic activity of TM oxides.^{127,130,148,151,152}

Elucidating the plausible involvement of lattice oxygen in highly active oxide catalysts requires the development of novel research approaches to address two important scientific issues: (1) the complex reaction mechanisms and (2) the stability of the TM oxide catalysts. This has motivated the development of *in situ* and operando characterisation technique such as isotope labelling combined with differential electrochemical mass spectrometry, *in situ* IR and Raman spectroscopies aiming to capture chemical information of reaction intermediates in mechanistic studies.¹⁴⁷ The study of the chemical state and the structure of the catalysts during the OER process has also been studied with operando XAS.¹⁹² Additional *in situ* characterisation studies with techniques such as ambient pressure X-ray photoelectron spectroscopy (NAP-XPS) to study the chemistry and energetics of the solid–liquid interface,^{193,194} may bring new opportunities to obtain a more realistic understanding of the relationship between electronic structure, adsorbate binding strength, and the OER catalytic activity.

The involvement of lattice oxygen in the OER of highly active catalyst leads to surface reconstructions and may also decrease the stability of the catalysts, especially at higher overpotentials. Therefore, the stability of the catalyst remains an important scientific issue in this field. Studying surface reconstruction phenomena could benefit from the use of well define surfaces of model samples. This experimental approach has been recently used in the description of mechanisms that connect the lattice

oxygen activation, metal dissolution, and amorphization in TM OER electrocatalysts.¹⁹⁵ Compared with ill-defined porous electrodes commonly used in OER studies, single crystal thin films permit a high degree of control over crystal facets, defects, and compositions, which could be used as model catalysts to gain a definitive structure–property relationships at a molecular level, and the study of surface reconstructions in a controlled way.
