# Structure and dynamics of 3'-aminoacetophenone and 4'-aminoacetophenone from rotational spectroscopy†

Giovanna Salvitti, <sup>a</sup> Silvia Sigismondi, <sup>a</sup> Sonia Melandri, <sup>a</sup>  
Juan Carlos López, <sup>b</sup> Susana Blanco <sup>\*b</sup> and Assimo Maris <sup>\*a</sup>

The rotational spectra of 4'-aminoacetophenone, and those of two conformers (*Z* and *E* arrangement of the C=O and NH<sub>2</sub> groups) of 3'-aminoacetophenone and their <sup>13</sup>C and <sup>15</sup>N isotopologues were investigated both in the microwave (2–8 GHz) and millimetre (59.6–74.4 GHz) frequency regions using chirped pulse Fourier transform and free-jet absorption techniques, respectively. The spectra consist of  $\mu_a$  and  $\mu_b$  type lines that show a hyperfine structure due to both the nuclear quadrupole coupling of the <sup>14</sup>N nucleus and the methyl internal rotation. Relative intensity measurements show that the *Z* form in 3'-aminoacetophenone is favoured with respect to *E* and the measured energy difference upper limit is about 5.5(1) kJ mol<sup>−1</sup>. Barriers to methyl internal rotation are  $V_3 = 7.04(2)$  and 6.530(6) kJ mol<sup>−1</sup> for 3'(*Z*)- and 4'-aminoacetophenone, respectively. Flexible model analyses of the amino inversion motion based on *ab initio* potential energy paths, suggest that the corresponding vibrational splitting increases up to 78% from aniline to 3'(*E*)-, 3'(*Z*), and 4-aminoacetophenone. However, due to supersonic expansion cooling, no splitting related to amine inversion is observed.

## 1 Introduction

Molecules are not rigid bodies but flexible objects characterized by internal motions leading to both vibrational modes and conformational complexity, which is related to the torsional degrees of freedom. The ensemble of the torsional angle's values define the so-called molecular conformational space and the energy of a molecule as a function of this ensemble is defined as the potential energy space (PES). Conformers correspond to the PES local minima, and their population at equilibrium is dependent on the temperature and quantified by the Boltzmann distribution. The interconversion between conformers is expected to occur along minimum energy paths, where their maxima are the transition states of the PES.

PES can be investigated through theoretical methods: quantum mechanics is used for small systems whereas molecular dynamics techniques are introduced as the molecular size increases (*i.e.* macromolecules). To determine the molecular structure of the most stable species, diffraction, nuclear

magnetic resonance, and rotational spectroscopy are the most used experimental techniques. However, obtaining information on the interconversion pathways is challenging. High-resolution spectroscopy can provide indirect information by measuring precise energy values for transitions between quantum-mechanical states. Actually, if two or more equivalent conformers exist and the interconversion barrier between them is small enough, the corresponding vibration states couple and the energy levels split due to the tunnelling effect. Using spectroscopic tools, it is possible to determine the size of this splitting and since it depends on the energy pathway, appropriate modelling can be used to characterize the interconversion energy barrier. Equivalent conformers can arise from the internal rotation of symmetric tops or planar frames, such as methyl and phenyl groups, respectively.<sup>1</sup> They can also originate from the inversion of a tetrahedral torsion angle, like the umbrella motion of ammonia.<sup>2</sup> Sometimes, interconversion occurs upon combined motions, as in the case of ring-puckering and pseudorotation in cyclic molecules.<sup>3</sup>

The gas phase constitutes the ideal medium to identify coupling effects because the torsional motions are not hindered by intermolecular interactions and high-resolution spectroscopy measurements are possible. In this respect, rotational and ro-vibrational spectroscopies, which also allow molecular structure characterization, have been proven to be valuable tools. For instance, from the free-jet millimetre-wave

spectrum of methacrylamide,<sup>4</sup> which is a small organic molecule with two C–C rotatable bonds ( $\text{CH}_3\text{--C}(\text{CH}_2)\text{--CONH}_2$ ), two conformers (one planar and the other with non-planar doubly degenerate skeletal arrangement) were detected and their energy difference was determined ( $4\text{ kJ mol}^{-1}$ ). Moreover, splittings due to the torsion around both the C–C bonds were observed and analyzed with appropriate Hamiltonian models<sup>5,6</sup> achieving the barrier for the methyl internal rotation of both planar and non-planar conformers ( $10.2$  and  $7.4\text{ kJ mol}^{-1}$ , respectively) as well as the interconversion barrier between the two equivalent non-planar forms ( $3.6\text{ kJ mol}^{-1}$ ). It is worth noting that in methacrylamide the amino group is part of an amide group and therefore its inversion motion is hindered because of resonance with the carbonyl group.

In addition to intramolecular effects, also intermolecular interactions can prevent the amine group inversion: when ammonia-like molecules form a non-covalent bond through their nitrogen lone pair the motion is blocked. This has been clearly observed in several molecular complexes, for instance, the hexafluorobenzene complexes with ammonia<sup>7</sup> and trimethylamine,<sup>8</sup> where the nitrogen lone pair points toward the  $\sigma$ -hole at the centre of the ring. Interestingly, in these species, another large amplitude motion is generated and observed: the free rotation between the monomers, which results in an overall symmetric-top geometry of the complex. Differently, in the absence of constraints, the amino group undergoes an inversion motion: the barrier and the splitting depending on the kind of groups bound to the nitrogen atom.

The term aminoacetophenone identifies a series of molecules constituted by a phenyl ring attached to an amine and acetyl side groups which are both characterized by large amplitude motions: the rotation inversion of the amine and the internal rotation of the whole acetyl group as well as its methyl group. In a previous paper, we studied 2'-aminoacetophenone (2AA) by chirped pulsed Fourier transform microwave spectroscopy and no effects due to large amplitude vibrations were observed.<sup>9</sup> Indeed, our study shows that due to the proximity of the amino and acetyl groups, an NH–O intramolecular hydrogen bond is formed that stiffens the overall molecular structure. However, as the two substituents are spaced on the ring and can not directly interact a different behaviour is expected, mainly affected by resonance and inductive effects. For this reason, we decided to investigate the rotational spectrum of *meta* and *para* isomers: 3'-aminoacetophenone (3AA) and 4'-aminoacetophenone (4AA) respectively, shown in Fig. 1.

## 2 Experimental methods

Commercial samples (Sigma Aldrich) of 3AA ( $\text{C}_8\text{H}_9\text{NO}$ , CAS no. 99-03-6, purity 97%, mp  $367\text{--}371\text{ K}$ , bp  $562\text{--}563\text{ K}$ ) and 4AA ( $\text{C}_8\text{H}_9\text{NO}$ , CAS no. 99-92-3, purity 99%, mp  $376\text{--}380\text{ K}$ , bp  $565\text{--}563\text{ K}$ ) were used without further purification. The gas phase compounds were studied in two different spectral regions using supersonic expansion conditions, in which the molecules reach very low rotational temperatures and the most stable forms are

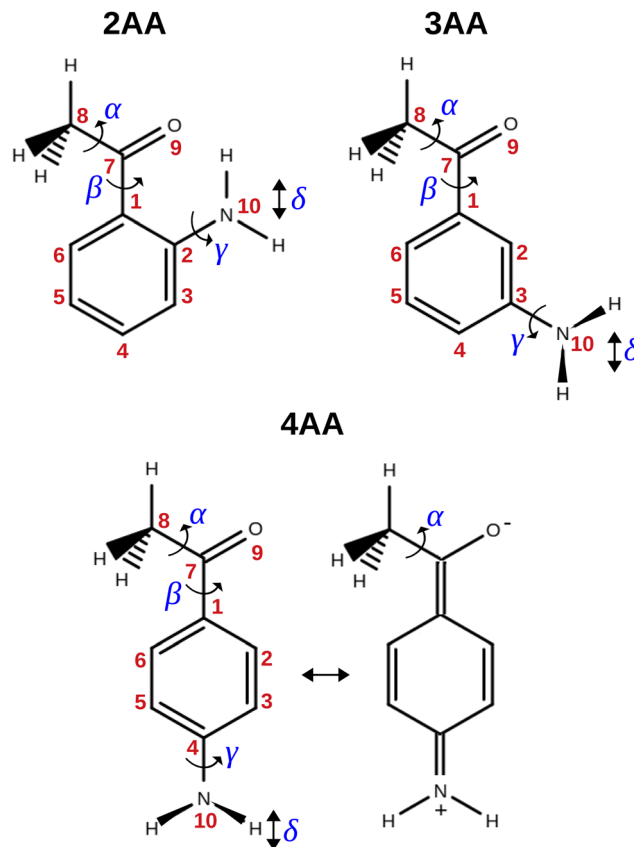

Fig. 1 Structure, atoms' numbering and torsional degrees of freedom of the isomers of aminoacetophenone and zwitterionic form of 4AA.

trapped in their energy minima. The broadband spectra were recorded using a chirped-pulse Fourier transform microwave spectrometer (CP-FTMW) with a heatable nozzle in the 2–8 GHz frequency interval.<sup>10</sup> The experimental conditions are briefly described. The supersonic jet was formed by the pulsed expansion of a Ne flow (2 bar) which drag the heated 3AA (408 K) or 4AA (403 K) vapour through a 0.8 mm nozzle with a repetition rate of 5 Hz. The sample was polarized by a 5  $\mu\text{s}$  chirped pulse amplified to 20 W, then the subsequent transient molecular emission spanning 40  $\mu\text{s}$  is recorded, and Fourier transformed to the frequency domain. For each gas pulse 8 polarization/detection frames were repeated. The accuracy of the frequency measurements is better than 10 kHz. The good signal-to-noise ratio obtained by the accumulation of 1.6 million spectra allowed us to measure the weak lines belonging to the <sup>13</sup>C and <sup>15</sup>N isotopologues observed in natural abundance. The spectrum in the 59.6–74.4 GHz frequency region was investigated using a Stark modulated free-jet absorption millimeter-wave (FJ-AMMW) spectrometer, the details of which have been described previously.<sup>11–13</sup> The 3AA and 4AA samples were heated to 408 and 403 K, respectively while a stream of argon at a stagnation pressure of 10 kPa flowed over it. The mixture was then expanded to about  $P_b = 0.5\text{ Pa}$  through a 0.3 mm diameter pinhole nozzle. The rotational temperature of the molecules in the jet was estimated to be 5–10 K.<sup>13</sup> The

estimated uncertainty for the measurements is about 50 kHz and lines separated by more than 300 kHz are distinguishable.

### 3 Computational methods

Geometry optimization and harmonic vibrational frequency calculations were run in order to characterize the minima on the PES. The potential energy functions of the internal motions were obtained through relaxed scans varying the involved coordinate on a regular grid. All calculations were performed with the Gaussian16<sup>‡</sup> software package (G16, Rev. A.03‡). Density functional theory (DFT) was applied for preliminary calculations. Valence triple- $\zeta$  quality Karlsruhe polarized type basis set (def2-TZVP)<sup>14</sup> was used in combination with Becke-three-parameters Lee–Yang–Parr hybrid density functional theory (B3LYP)<sup>15,16</sup> corrected by the D3 version of Grimme's empirical dispersion with Becke–Johnson (BJ) damping.<sup>17,18</sup> *Ab initio* calculations were performed using valence triple- $\zeta$  quality Dunning correlation consistent polarized type basis set augmented with diffuse functions (aug-cc-pVTZ)<sup>19</sup> in combination with Møller–Plesset second-order perturbation theory (MP2).<sup>20</sup>

### 4 Results

According to quantum-mechanical calculations, the structures of 4AA and 3AA are characterized by the acetyl symmetry plane being coplanar to the phenyl ring and the amine having a pyramidal arrangement, as shown in Fig. 2. Only one species is expected for 4AA, whereas for 3AA, depending on the orientation of the acetyl group, two conformers are possible, where the carbonyl and amine groups are on the same or opposite sides with respect to the C7C1C2C3 skeletal frame. Extending the meaning of *zusammen* and *entgegen* configurations, we will label these conformers as 3AA-Z and 3AA-E, respectively.

The simulations based on the predicted spectroscopic parameters and energy values listed in Tables 1–3 allowed us to identify, for each of the three species, several  $\mu_a$  and  $\mu_b$ -type rotational transition lines. In agreement with the calculated relative energies and dipole moment component values, the spectrum of 3AA-Z is more intense than the spectrum of 3AA-E. All the rotational transition lines recorded by CP-FTMW in the 2–8 frequency region show a hyperfine structure (see for instance Fig. 3) due to the interaction of the <sup>14</sup>N nuclear quadrupole with the electric field gradient at nitrogen. Also, it is worth noting that, despite the not negligible value expected for the electric dipole moment along the *c* direction (0.8–1 D), no corresponding transition lines were observed.

Ray's asymmetry parameter<sup>21</sup> is  $\kappa \simeq -0.9$  for 4AA and  $\kappa \simeq -0.7$  for 3AA-Z and 3AA-E, classifying the observed species as asymmetric prolate rotors. As a first approach, the lines were assigned using the CALPGM program suite<sup>22</sup> through direct diagonalization of the following Hamiltonian:

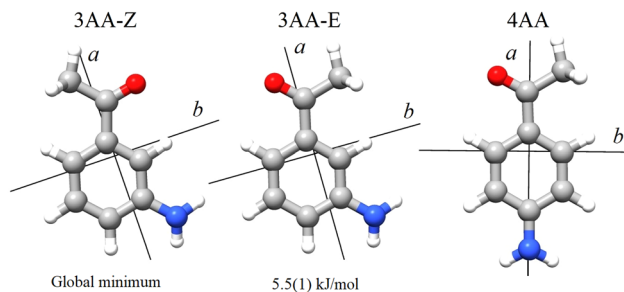

Fig. 2 Principal axis system of 3' and 4'-aminoacetophenone.

$$\hat{H} = \hat{H}_{\text{ROT}} + \hat{H}_{\text{CD}} + \hat{H}_{\text{NQC}} \quad (1)$$

where  $\hat{H}_{\text{ROT}}$  represents the rigid rotor related to the *A*, *B*, and *C* rotational constants,  $\hat{H}_{\text{CD}}$  takes into account the centrifugal distortion effect and  $\hat{H}_{\text{NQC}}$  is the operator associated with the coupling of the <sup>14</sup>N nuclear spin (*I* = 1) with the overall rotation. This coupling leads to a hyperfine structure of the rotational transition lines. The *S*-reduction in *I*-representation was used in the fit and different uncertainties were applied to CP-FTMW (15 kHz) and FJ-AMMW (50 kHz) data. The details of the spectral features are discussed below.

#### 4.1 Rotational spectrum of 4AA

The broadband spectrum of 4AA is shown in Fig. S1 of the ESI† 22 intense *R*- $\mu_a$ -type transition lines with rotational quantum numbers from  $J'' = 1$  to  $J'' = 5$ , 7 *R*- $\mu_b$  with rotational quantum numbers  $J'' = 0$ –7 and 14 *Q*- $\mu_b$ -type transition lines with rotational quantum numbers  $J'' = 1$ –9 were assigned in the 2–8 GHz spectral region. The  $3_2-2_2$  and  $4_2-3_2$   $\mu_a$ -type transition lines, and the  $7_{2,5}-7_{1,6}$   $\mu_b$ -type transition line, are further split due to the methyl internal rotation effect (*A/E* components) and six  $\mu_b$ -type transition lines show a splitting of about 0.05 MHz. Several  $K_a$ -asymmetry degenerate or almost degenerate *R*- $\mu_b$ -type transition lines with  $J'' = 8$ –19 and  $K_a'' = 6$ –10 were assigned in the 59.6–74.4 GHz frequency region. Due to methyl internal rotation, each is a triplet with a central line and two weaker side peaks that have been assigned to *E*-type  $\mu_c$ -forbidden lines.

The overall set of detected lines was analysed using the combined axis method (CAM)<sup>23</sup> implemented in the XIAM program,<sup>5</sup> which fits a set of spectroscopic constants common to both the *A* and *E* states and directly supplies the methyl internal rotation barrier. The values of the reduced internal rotation constant ( $F_0$ ) and the angle between the internal rotation axis and the *a* principal inertial axis ( $\angle ia$ ) were fixed to those of the MP2/aug-cc-pVTZ calculated structure, whereas  $\angle ic$  was arbitrarily fixed to 0. A complete line list can be found in the ESI† (Table S1) while the determined rotational constants are given in Table 1.

#### 4.2 Rotational spectrum of 3AA-Z

The broadband spectrum of 3AA is shown in Fig. S2 of the ESI† 18 intense *R*- $\mu_a$ -type transition lines with rotational quantum numbers from lower  $J'' = 1$  to  $J'' = 4$ , 10 *R*- $\mu_b$  type transition lines

<sup>a</sup>  $A$ ,  $B$  and  $C$  are the rotational constants.  $D_J$ ,  $D_{JK}$  and  $D_K$  are the quartic centrifugal distortion constants.  $\kappa = (2B - A - C)/(A - C)$  is the Ray parameter.  $M_{gg}$  ( $g = a, b$  or  $c$ ) are the planar moments of inertia.  $\mu_g$  ( $g = a, b$  or  $c$ ) are the electric dipole moment components, Yes or No indicated if  $a$ -,  $b$ - or  $c$ -type transitions have been observed.  $\chi_{aa}$ ,  $\chi_{bb}$  and  $\chi_{cc}$  are the quadrupole coupling tensor diagonal elements for <sup>14</sup>N atom.  $V_3$  is the internal rotation barrier for the methyl top.  $N$  is the number of quadrupole hyperfine components fitted.  $\sigma$  is the rms deviation of the fit.  $E_e$  is the electronic energy.  $E_0$  is the zero point energy. <sup>b</sup> Standard errors in parentheses in units of the last digits. <sup>c</sup> The value of  $F_0 = \hbar^2/(2I_x)$ , where  $I_x$  is the inverse of the moment of inertia of the methyl top, and the angle between the methyl top axis and the  $a$ -axis  $\delta$  were fixed to the *ab initio* values in the fit:  $F_0 = 159.533$  GHz,  $\delta = 1.02965$  rad.

with rotational quantum numbers from  $J'' = 0$  to  $J'' = 5$  and 17  $Q$ - $\mu_b$ -type transition lines with rotational quantum numbers from  $J'' = 2$  to  $J'' = 8$  were assigned in the 2–8 GHz spectral region. 5 transition lines are further split due to the methyl internal rotation effect and 9 transition lines show an additional splitting of about 0.05 MHz. Additional 9  $R$ - $\mu_b$ -type transition lines with  $J'' = 11$ –16 and  $K_a'' = 9$ –11 were detected in the 59.6–74.4 GHz frequency region. As for 4AA, they are characterised by methyl internal rotation hyperfine structure. The overall set of lines was fitted with the XIAM program, determining the spectroscopic constants given in Table 2. A complete line list can be found in the ESI† (Table S2).

### 4.3 Rotational spectrum of 3AA-E

17  $R$ - $\mu_a$ -type transition lines with rotational quantum numbers from  $J'' = 1$  to  $J'' = 4$ , 10  $R$ - $\mu_b$  with rotational quantum numbers from  $J'' = 0$  to  $J'' = 5$  and 20  $Q$ - $\mu_b$ -type transition lines with rotational quantum numbers from lower  $J = 2$  to  $J = 7$  were assigned. Few weak  $R$ - $\mu_b$ -type transition lines with  $J'' = 13$ –17 and  $K_a'' = 10$ –12 were assigned in the 59.6–74.4 GHz frequency region. A complete line list can be found in the ESI† (Table S3) while the determined rotational constants are given in Table 3.

### 4.4 Isotopologues

Thanks to the good signal-to-noise ratio of CP-FTMW spectrometer, some transition lines of the <sup>13</sup>C isotopologues of 4AA ( $\mu_a$ -type) and 3AA-Z ( $\mu_a$ - and  $\mu_b$ -type) were observed in natural abundance. Their rotational constants were determined using the CALPGM program suite,<sup>22</sup> fixing the value of nuclear coupling constants to those determined for the parent species. Unsplit <sup>15</sup>N-isotopologue lines were also observed and assigned for 4AA. A complete line list can be found in the ESI† (Tables S4–S20) while the determined rotational constants are given in the bottom part of Tables 1 and 2, respectively for 4AA and 3AA-Z.

## 5 Discussion

### 5.1 Molecular structure

First inspection of the rotational constants, shows that there is a reasonable agreement between the theoretical values, which refer to the equilibrium geometry ( $r_e$ ) in the PES, and the experimental ones, which describe the molecule in its vibrational ground state ( $r_0$ ). The theoretical values of the  $B$  and  $C$

<sup>a</sup> Constants as defined in Table 1. <sup>b</sup> Standard errors in parentheses in units of the last digits. <sup>c</sup> The value of  $F_0 = \hbar^2/(2I_a)$ , where  $I_a$  is the inverse of the moment of inertia of the methyl top, and the angle between the methyl top axis and the  $a$ -axis  $\delta$  were fixed to the *ab initio* values in the fit:  $F_0 = 159.485$  GHz,  $\delta = 0.74466$  rad.

rotational constants calculated at the B3LYP-D3(BJ)/def2-TZVP and MP2/aug-cc-pVTZ levels of calculations differ by about 1 MHz or less, whereas the values for  $A$  differ by about 10–15 MHz.

The *ab initio* values are closer to the experimental data than the DFT ones. Because of the vibration motions, the observed rotational constants are smaller than those computed in the harmonic approximation, the difference being about 1–9‰ with respect to the *ab initio* results. This effect can perhaps be better appreciated by comparing the planar moments of inertia (Tables 1 and 2), which are linear combinations of the moment of inertia that measure the distribution of the atoms' masses ( $m_i$ ) along the principal inertial axes ( $a$ ,  $b$  and  $c$ ), i.e.:

$$M_{cc} = \frac{+I_{aa} + I_{bb} - I_{cc}}{2} = \sum_i m_i \cdot c_i^2 \quad (2)$$

As regards the value of  $M_{cc}$ , it provides rough information on the out-of-plane atoms, even if the  $ab$  plane does not coincide exactly with that of the phenyl ring. The  $M_{cc}$  value is  $1.79 \text{ u}\text{\AA}^2$  for acetophenone<sup>24</sup> due to the methyl group contribution and  $0.20 \text{ u}\text{\AA}^2$  for aniline<sup>25</sup> due to that of the amine group. The sum of these values ( $1.99 \text{ u}\text{\AA}^2$ ) should give us a rough estimation for aminoacetophenones. Consistently, the experimental values are 2.04, 2.00 and  $1.94 \text{ u}\text{\AA}^2$  for 3AA-E, 3AA-Z and 4AA, respectively. The lower value of 4AA could depend on the mesomeric effect for which a zwitterionic resonant planar structure exists

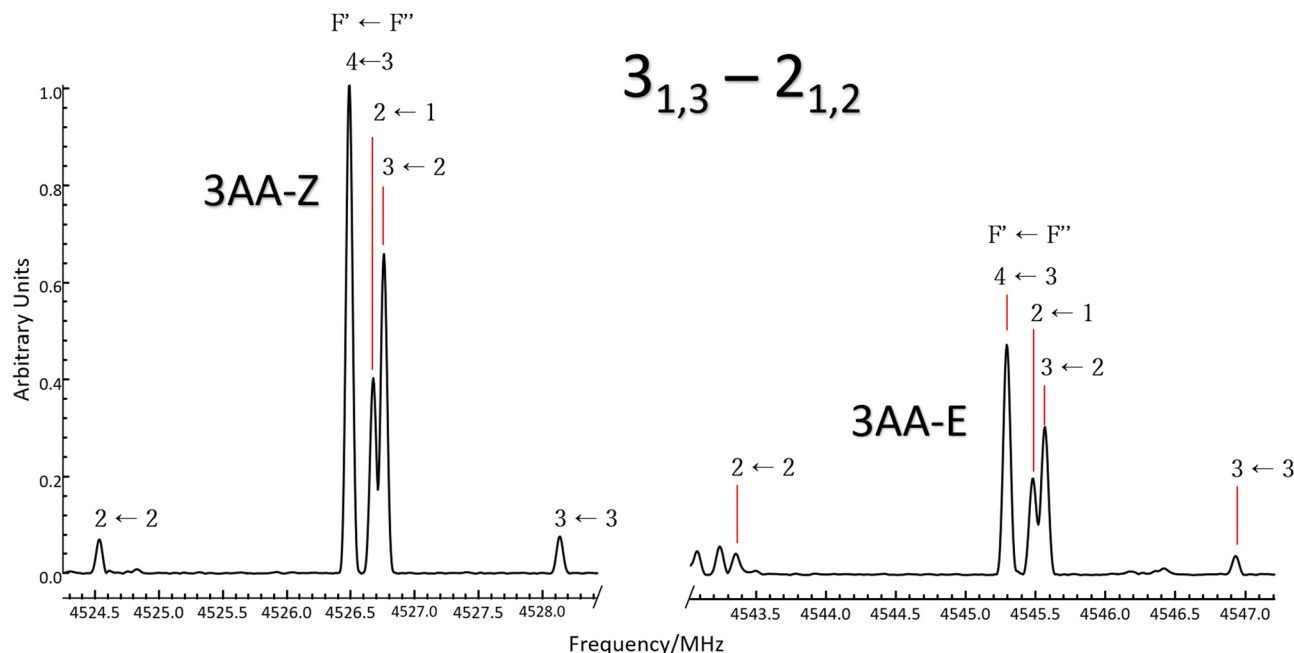

Fig. 3 Excerpt of the CP-FTMW spectrum comparing the  $3_{1,3} \leftarrow 2_{1,2}$   $\mu_a$ -type transition line of 3AA-Z (left) and 3AA-E (right). Lines are split by  $^{14}\text{N}$  nuclear quadrupole coupling interactions and a 1:0.5 intensity ratio between conformers is observed.

as depicted in Fig. 1. However, for 2AA a smaller value similar to that of acetophenone was determined ( $1.80 \text{ uÅ}^2$ ) and ascribed to a planar arrangement of the amine group constrained by an intramolecular hydrogen bond.<sup>9</sup>

Experimental information on the atoms' position was achieved using Kraitchmans's method based on the assumption that different isotopologues share the same geometry.<sup>26</sup> The resulting substitution coordinates ( $r_s$ ), the sign of which cannot be determined, are listed and compared to the computed equilibrium ones ( $r_e$ ) in Tables 4 and 5 for 4AA and 3AA-Z, respectively. Usually, the knowledge of the absolute value of the substitution coordinates allows for a straightforward assignment of the coordinates themselves to the appropriate atom. This was shown for example for *cis*-verbenol whose ten carbon atoms positions are clearly distinguishable.<sup>27</sup> However, despite the absence of any element of symmetry, it can happen that, apart from the sign, two atoms have similar coordinates, making the assignment difficult. In 4AA, we find three pairs of this kind: C2/C6, C3/C5 and C4/C7. Comparison with theoretical data allows for a reliable assignment of C2/C6 and C3/C5, whereas concerning C4 and C7 the assignment remains uncertain.

## 5.2 Relative intensity of 3AA conformers

Conformer 3AA-Z is calculated to be more stable than 3AA-E by  $235 \text{ cm}^{-1}$  at the MP2/aug-cc-pVTZ level and the inclusion of zero-point vibrational contribution slightly decreases this value to  $224 \text{ cm}^{-1}$ . Evaluation of the free energy values in the harmonic and rigid rotor approximations further lowers the difference between conformers to  $201 \text{ cm}^{-1}$ .

It is worth noting that similar values are estimated at the B3LYP-GD3(BJ)/def2-TZVP level of calculation (245, 244 and

$224 \text{ cm}^{-1}$ , respectively). At the thermal equilibrium, in the experimental pre-expansion conditions ( $T = 408 \text{ K}$ ), the *ab initio* free energy difference corresponds to a relative abundance  $N_Z:N_E = 1:0.5$ . According to the theoretical electric dipole moment components, the intensity ratio of the rotational transition lines can be estimated as  $I_Z^a:I_E^a = 1:1.2$  and  $I_Z^b:I_E^b = 1:0.8$ . Actually, if we compare the same rotational transition lines (see for instance Fig. 3), those of 3AA-Z are always more

intense than the 3AA-E ones:  $I_Z^a:I_E^a = 1:0.5$  and  $I_Z^b:I_E^b = 1:0.3$ , confirming that 3AA-Z is the most stable conformer. The reason behind this preferred arrangement is uncertain, but it is worth noting that the electric dipole moment is less in the most stable species ( $\mu_Z = 3.0$  and  $\mu_E = 4.3$  D).

However, the experimental evidence and theoretical landscape do not match perfectly, meaning that either the calculated energy difference is underestimated or that a partial conformational relaxation occurs during the supersonic expansion. In the hypothesis that no relaxation takes place, the relative energy of 3AA-E derived from the relative intensity measurements is about  $460(10) \text{ cm}^{-1}$ . Interestingly, an X-ray diffraction study identified 3AA-Z as a ligand of the apo form cyclophilin-D isomerase, see <https://doi.org/10.2210/pdb3R59/pdb>.<sup>28</sup>

### 5.3 Nuclear quadrupole coupling interaction

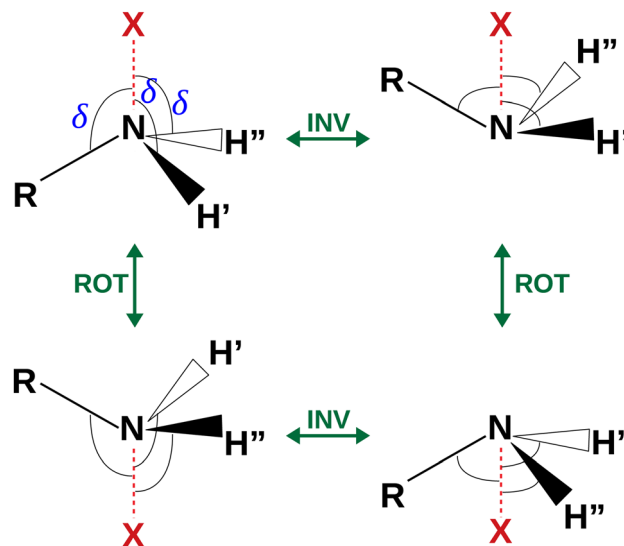

The  $^{14}\text{N}$  nuclear quadrupole coupling constants of the aminoacetophenone isomers are compared to those of aniline in Table 6. The values of 4AA and aniline are similar, due to the analogous orientation of the principal axis system with respect to the amine group. As regards 3AA, the rotation of the *ab* inertial plane is reflected by the change on the  $\chi_{aa}$  and  $\chi_{bb}$  values, whereas the  $\chi_{cc}$  values, which refer to the direction approximately perpendicular to the ring are only slightly modified.

### 5.4 Internal molecular dynamics

The conformational space of aminoacetophenones is described by the four torsion coordinates shown in Fig. 1 and labelled  $\alpha$ ,

**Table 6**  $^{14}\text{N}$  nuclear quadrupole coupling constants of aniline and aminoacetophenone isomers

	Aniline <sup>25</sup>	4AA	3AA-Z	3AA-E	2AA
$\chi_{aa}/\text{MHz}$	2.34(6)	2.424(7)	2.137(6)	2.125(7)	1.193(7)
$\chi_{bb}/\text{MHz}$	1.86(6)	1.866(2)	2.143(9)	2.126(5)	2.608(4)
$\chi_{cc}/\text{MHz}$	−4.20(6)	−4.289(2)	−4.279(9)	−4.251(5)	−3.801(4)

**Fig. 4** Sketch of the four equivalent minima arising from the rotoinversion of the amine group.  $\delta$  is the angle used to describe the inversion of the amine group.

$\beta$ ,  $\gamma$  and  $\delta$ . The dihedral angles  $\alpha = \text{HC8C7C1}$  and  $\beta = \text{C8C7C1C2}$  concern the internal rotation of the methyl and the acetyl groups, respectively. The corresponding DFT 2D-PESs are shown in Fig. 5 and 6 for the two isomers. As regards the methyl internal rotation, a threefold path is found where barriers are approximately  $494$ ,  $464$  and  $411 \text{ cm}^{-1}$  for 3AA-Z, 3AA-E and 4AA, respectively. Further *ab initio* investigations raise these values by about  $100 \text{ cm}^{-1}$ , in particular:  $535$ ,  $556$  and  $514 \text{ cm}^{-1}$ , respectively. For a threefold path, splitting of the energy levels into a non-degenerate A-level and a doubly degenerate E-level is expected. Accordingly, several split lines were detected, allowing us to determine the methyl internal rotation barriers of both 3AA-Z ( $V_3 = 595(1) \text{ cm}^{-1}$ ) and 4AA ( $V_3 = 545.7(5) \text{ cm}^{-1}$ ). Comparison with the analogous compound acetophenone ( $V_3 = 7.50(3) \text{ kJ mol}^{-1}$  corresponding to  $627(3) \text{ cm}^{-1}$ <sup>24</sup>) suggests that insertion of an amine group in the phenyl ring lowers the methyl internal rotation barrier and that substitution in *para* is more effective than substitution in *meta*. The A/E energy difference has been estimated to be  $37$  and  $58 \text{ MHz}$  for 3AA-Z and 4AA, respectively.

The dihedral angle  $\beta = \text{C8C7C1C2}$ , concerns the rotation of the acetyl group. Rotation around the C1–C7 bond leads to conformers *Z* ( $\beta = 180^\circ$ ) and *E* ( $\beta = 0^\circ$ ) separated by a  $2100 \text{ cm}^{-1}$  barrier for 3AA (Fig. 5) and to two equivalent species separated by a  $2800 \text{ cm}^{-1}$  barrier for 4AA (Fig. 6). The fundamental band for this torsion in acetophenone has been observed at  $49.5 \text{ cm}^{-1}$  and a twofold potential model barrier provided a barrier of  $1103 \text{ cm}^{-1}$ .<sup>29</sup> A subsequent microwave spectroscopy study confirmed that the acetyl group is coplanar to the phenyl ring.<sup>30</sup>

The coordinates  $\gamma = \text{XNCC}$  and  $\delta = \angle \text{XNC} = \angle \text{XNH}$  describe the amine group's rotation and inversion, respectively. To define them, we introduced a point X (see Fig. 1) whose position is determined by the constraint that the N–X direction makes equal angles ( $\delta$ ) with the three amine bonds. In the case of  $C_{3v}$  molecular symmetry (*i.e.* ammonia), the N–X direction is that of

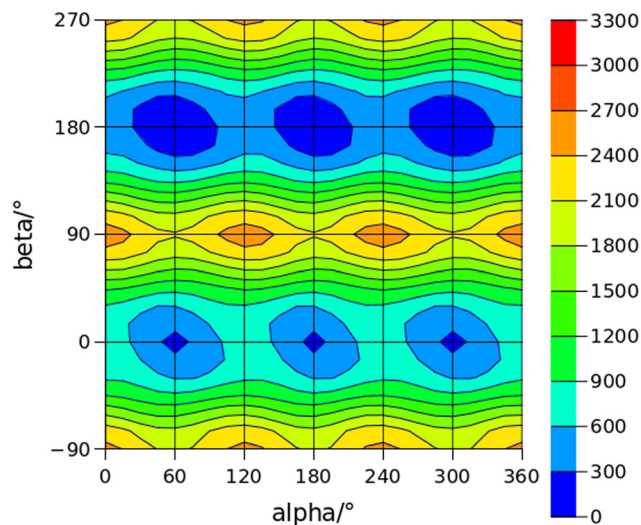

Fig. 5 2D-PES for the methyl and acetyl internal rotations ( $\alpha$  = HC8C7C1 and  $\beta$  = C8C7C1C2, respectively) of 3AA at the B3LYP(D3BJ)/def2-TZVP level of calculation using a sampling step of  $15^\circ$ . Energy values are given in  $\text{cm}^{-1}$ .

the  $C_3$  symmetry axis. According to this definition,  $\delta$  can be used as the inversion coordinate. For  $\delta = (\pi/2)$  the amino group is planar whereas for  $\delta = (\pi/2 \pm x)$  two equivalent non-planar geometries are generated.  $x$  is called the pyramidalization angle. It is worth noting that two equivalent non-planar geometries are also generated upon rotation of the amino group around the N-C bond. Hence, four equivalent conformers exist, corresponding to the position of the amine hydrogen atoms above and below the phenyl plane. However, a comparison of the *ab initio* potential energy paths for the rotation (Fig. 7) and inversion (Fig. 8) motions, shows that the energy barrier for the amine rotation (about  $2000 \text{ cm}^{-1}$ ) is larger than that of amine inversion (about  $400 \text{ cm}^{-1}$ ). The estimated inversion barriers are similar to those of other amine compounds for which values spanning the  $200\text{--}2000 \text{ cm}^{-1}$  range were

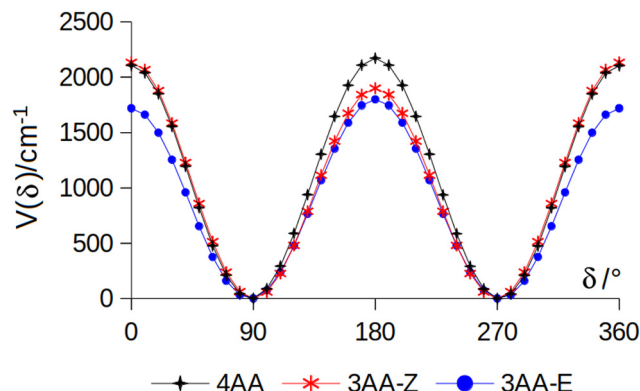

Fig. 7 Potential energy function for the amine internal rotation calculated at the MP2/aug-cc-pVTZ level using a sample step of  $10^\circ$ .

determined by PES modelling based on the experimental observations (see Table 7). For most of them a double minimum model has been used but for methylamine<sup>31</sup> and aminocyclobutane<sup>32</sup> a two-dimensional model taking into account also the amine rotation had to be used to explain all the observed spectral features. Moreover, it is worth noting that depending on the used model, different values can be determined. For instance, the barrier for aniline was estimated to be  $525 \text{ cm}^{-1}$  by Larsen *et al.*<sup>33</sup> and  $392 \text{ cm}^{-1}$  by Fehrensens *et al.*,<sup>34</sup> respectively. Interestingly, the *ab initio* value ( $472 \text{ cm}^{-1}$ ) lies in between the experimental findings, indicating that the calculations are quite reliable. For this reason, we decided to apply the one-dimensional flexible model of Meyer<sup>35</sup> to the theoretical parameters in order to estimate the inversion splitting in 3AA and 4AA, using aniline as a benchmark.

### 5.5 Flexible model

A double minimum non-periodic function based on two parameters was used to describe the amine inversion potential path:

$$V(x) = B \cdot \left[ 1 - \left( \frac{x}{x_c} \right)^2 \right]^2 \quad (3)$$

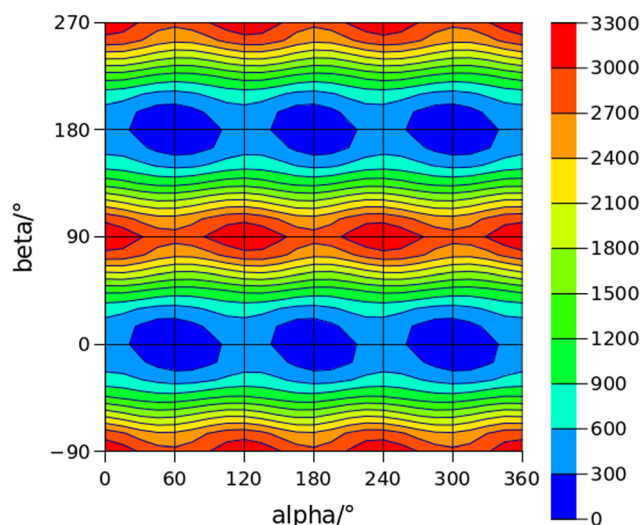

Fig. 6 2D-PES for the methyl and acetyl internal rotations ( $\alpha$  = HC8C7C1 and  $\beta$  = C8C7C1C2, respectively) of 4AA at the B3LYP(D3BJ)/def2-TZVP level of calculation using a sampling step of  $15^\circ$ . Energy values are given in  $\text{cm}^{-1}$ .

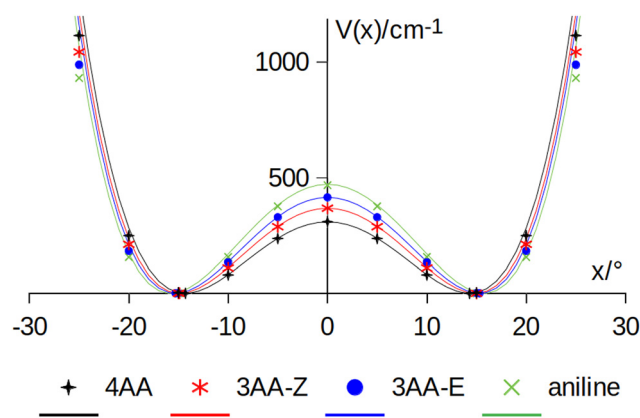

Fig. 8 Amine inversion potential energy function. Points are calculated at the MP2/aug-cc-pVTZ level using a sample step of  $5^\circ$ . Lines correspond to the double minimum function described in eqn (3) using the theoretical barriers and pyramidalization angles ( $x$ ) listed in Table 8.

Table 7 Amine inversion barrier ( $B/\text{cm}^{-1}$ )

Ammonia <sup>2</sup>	2020(12)
Methylamine <sup>31</sup>	1943(130)

where  $x$  is the pyramidalization angle, the planar arrangement being  $x = 0$ ,  $x_e$  is the value of the inversion coordinate at the equilibrium position, and  $B = V(0)$  is the barrier to inversion. The *ab initio* equilibrium angle and the barrier listed in Table 8 were used to define  $V(x)$ , fairly reproducing the overall *ab initio* path, as shown in Fig. 4.

A numerical simulation was performed by exploring a  $100^\circ$  range with 80 grid mesh points, obtaining the vibrational splitting ( $\Delta E$ ) also given in Table 8. The model satisfactorily reproduces the ground state splitting of aniline, the experimental value being  $40.9 \text{ cm}^{-1}$  and the modelled one  $41.6 \text{ cm}^{-1}$ . *Ab initio* calculations suggest that the inversion barrier and the pyramidalization angle decrease in going from aniline to 3AA-E, 3AA-Z and 4AA. Notably, this kind of planarization of the amine group is in agreement with the trend of the observed planar moment of inertia along the  $c$ -axis:  $M_{cc}$  (3AA-E) = 2.04,  $M_{cc}$  (3AA-Z) = 2.00 and  $M_{cc}$  (4AA) = 1.94  $\text{u}\text{\AA}^2$ . Accordingly, the predicted splittings increase up to  $75 \text{ cm}^{-1}$  for 4AA.

Considering that the split eigenstates are symmetric and antisymmetric with respect to the inversion coordinate and that the  $\mu_c$  electric dipole moment component changes its sign along the same inversion coordinate, then the selection rules imply that  $\mu_a$ - and  $\mu_b$ -intrastate and  $\mu_c$ -interstate type transitions lines should be observed. According to the flexible model results, interstate transitions will lie in the far-infrared spectral region and only intrastate transitions will take place in the microwave range. Actually, in the case of aniline, two series of lines separated by a few MHz have been observed and assigned to the symmetric and antisymmetric states.<sup>36</sup> Differently, in the spectra of 3AA and 4AA we only observed a small splitting in some of the  $\mu_b$ -type transition lines, which is not consistent with the expected trend. Therefore, we suppose that molecular cooling takes place during the supersonic expansion, depopulating

the antisymmetric state. To support this interpretation, it is crucial to mention that splitting is usually observed in conventional microwave spectroscopy performed in a static cell (see compounds listed in Table 7), while there was no splitting observed in other substituted anilines that underwent examination in supersonic jets, including 3-aminophenol<sup>37</sup> and 4-aminobenzonitrile.<sup>38</sup>

## 6 Conclusions

The rotational spectra of 4AA, two conformers of 3AA and 17 isotopologues were observed and assigned for the first time under supersonic expansion conditions. The rotational, quartic centrifugal distortion and  $^{14}\text{N}$  nuclear quadrupole coupling constants were determined, opening future investigations in higher frequency regions as well as molecular detection in the astrophysical and analytical fields. Even though the acetyl and amine groups cannot directly interact, both quantum mechanical calculations and relative intensity measurements clearly show that the preferred arrangement in 3AA is the one with the smaller electric dipole moment. This conformation is the one with the carbonyl and amine groups on the same side with respect to the phenyl ring.

*Ab initio* calculations suggest that the amine inversion barrier of the amino group decreases upon the substitution of a hydrogen atom with an acetyl group and that substitution in *para* position is more effective than substitution in *meta*, probably due to the mesomeric effect. The results also show that the orientation of the acetyl group in 3AA plays a role since the barrier is lower for 3AA-E with respect to the one in 3AA-Z. Furthermore, theoretical and experimental evidence shows that amine substitution affects the methyl internal rotation motion, lowering the hindering barrier. Again the substitution in *para* position is more effective.
