Semiconductors are ubiquitous gain media for coherent light sources. Solution-processed three-dimensional (3D) halide perovskites (e.g., $\text{CH}_3\text{NH}_3\text{PbI}_3$) with their outstanding room temperature optical gain properties are the latest members of this family. Their two-dimensional (2D) layered perovskite counterparts with natural multiple quantum well structures exhibit strong light–matter interactions and intense excitonic luminescence. However, despite such promising traits, there have been no reports on room temperature optical gain in 2D layered perovskites. Herein, we reveal the challenges towards achieving amplified spontaneous emission (ASE) in the archetypal $(\text{C}_6\text{H}_5\text{C}_2\text{H}_4\text{NH}_3)_2\text{PbI}_4$ (or PEPI) system. Temperature-dependent transient spectroscopy uncovers the dominant free exciton trapping and bound biexciton formation pathways that compete effectively with biexcitonic gain. Phenomenological rate equation modeling predicts a large biexciton ASE threshold of $\sim 1.4 \text{ mJ cm}^{-2}$, which is beyond the damage threshold of these materials. Importantly, these findings would rationalize the difficulties in achieving optical gain in 2D perovskites and provide new insights and suggestions for overcoming these challenges.

Introduction

Organic–inorganic lead halide perovskites have emerged as technologically important semiconductors due to recent discoveries of their outstanding optoelectronic properties.^{1–4} They can be categorized based on their structural dimensionality, with 2D (A_2BX_4 formula) and 3D (ABX_3 formula) perovskites being the most studied materials. While disproportionate attention has

been given to 3D perovskites for photovoltaics, there has also been a recent surge of interest in their light emitting^{1,5–7} and optical gain properties.^{3,8–11} 2D perovskites had dominated the limelight in the past decades due to their potential for applications in light emitting diodes.^{12–16} Nonetheless, reports of optical gain in solution-processed 2D perovskite thin films are few and far between: out of 28 perovskite optical gain reports available to date, there is only one early report by Kondo *et al.*¹⁷ that claimed 2D perovskite cavity lasing at 16 K (see Fig. S1, ESI†). Although this report showed evidence of narrow emission linewidth at higher pump intensity, the light-in-light-out data presented did not indicate a clear transition from spontaneous emission to stimulated emission. As Samuel *et al.* pointed out, the lasing phenomenon should satisfy four criteria,¹⁸ namely: (1) narrow emission linewidth, (2) clear threshold associated with emission intensity and linewidth, (3) tunable light emission with laser cavity and gain medium, and (4) beam-like output (see Fig. S2, ESI†). It is important to ensure that all these criteria are fulfilled to eliminate phenomena with similar signatures from luminescent micro-cavities and waveguiding effects that could be mistakenly assigned as lasing. As such, it is highly possible (in view of the limited data available from the manuscript) that the “lasing” reported by Kondo *et al.*¹⁷ could in fact be a case of a luminescent microcavity or waveguiding effect (or a combination of both). Although the possibility of attaining

lasing from 2D perovskites cannot be totally ruled out, it is surprising that reports on optical gain from 2D perovskites are scarcely available. 2D perovskites (e.g., $(\text{C}_6\text{H}_5\text{C}_2\text{H}_4\text{NH}_3)_2\text{PbI}_4$ (hereafter called PEPI)), which exhibit a strong excitonic green emission, could be potential gain materials for overcoming the “green gap” in semiconductor lasers.¹⁹ In particular, PEPI has been extensively investigated for light emission applications in the 1990s and early 2000.^{13,14,20} The naturally formed quantum well in 2D perovskites is also attractive for integration into electrically pumped gated green lasers.²¹ The excellent in-plane mobility experienced by charge carriers in the inorganic quantum well is also expected to be better than four-level conjugated organic semiconductor systems which exhibit ASE.²² Unfortunately, the limited reports on 2D perovskite lasing clearly unpin the challenges in achieving optical gain from these materials. Detailed photophysical insights into the relaxation processes of the photoexcited species, as well as the dominant factors limiting the optical gain, are therefore urgently required.

Herein, we present a detailed photophysical study on solution-processed PEPI thin films using temperature and pump-fluence dependent photoluminescence (PL) spectroscopy. Room temperature PL spectroscopy using high laser pump fluence (of the order of $100 \mu\text{J cm}^{-2}$) revealed a dominating free excitonic emission peak (peak 1) with a notable absence of ASE. Low temperature PL revealed a more significant bound excitonic emission peak (peak 2) with a third biexcitonic emission peak (peak 3) appearing at higher laser excitation fluence ($\sim 30 \mu\text{J cm}^{-2}$). Nonetheless, no optical gain (i.e., ASE) can be observed from PEPI at low temperatures using high laser fluence (of the order of $100 \mu\text{J cm}^{-2}$). The Arrhenius plot from the temperature dependent PL revealed a small energy difference ($\sim 10 \text{ meV}$) between peak 1 and peak 2 emission levels and suggests dependencies between these levels. Significant PL quenching of peaks 2 and 3 upon surface passivation of PEPI points to a surface origin of these two peaks. Importantly, our findings shed light on the interplay between competing relaxation channels in PEPI, which could potentially limit biexcitonic ASE in PEPI. This limitation concurs with theoretical modeling which shows a large biexcitonic ASE threshold beyond the damage threshold of PEPI. From these findings, we provided suggestions for overcoming the optical gain challenges in 2D perovskites.

Experimental

Thin film fabrication

All the chemicals were purchased from Sigma-Aldrich. $\text{C}_6\text{H}_5\text{C}_2\text{H}_4\text{NH}_3\text{I}$ was prepared by adding 5.45 ml of HI (57%) to the mixture of 5 g of $\text{C}_6\text{H}_5\text{C}_2\text{H}_4\text{NH}_2\text{I}$ and 5 ml of methanol at 0°C . The reaction mixture was further stirred for an hour at room temperature. Excess solvent was then removed using the rotary evaporator at 50°C to obtain a white powder mass. The powder was then washed with cold ether several times and dried to obtain $\text{C}_6\text{H}_5\text{C}_2\text{H}_4\text{NH}_3\text{I}$ powder. PEPI solution was subsequently obtained by dissolving stoichiometric amounts

(2:1) of $\text{C}_6\text{H}_5\text{C}_2\text{H}_4\text{NH}_3\text{I}$ and PbI_2 in *N,N*-dimethylformamide. The weight concentration of this solution was fixed at 25 wt% for PL measurements. Two samples are fabricated for PL measurements. The first sample was fabricated by spin-coating the solution on a cleaned quartz substrate at 4000 rpm for 30 seconds. The resulting film was subsequently annealed at 100°C for 30 minutes. The second sample was fabricated by spin-coating an additional PMMA (10 mg mL^{-1} in chloroform) layer on the perovskite film and subsequently annealing it at 100°C for 15 minutes. Both samples are fabricated in a glovebox filled with inert nitrogen gas.

Low temperature steady-state and time-resolved photoluminescence spectroscopy

Femtosecond excitation pulses (wavelength, 400 nm) were obtained *via* second harmonic generation of pulses from a Coherent Libra regenerative amplifier (1 KHz, 50 fs), which was seeded by a Coherent Vitesse oscillator. The samples were mounted in a cryostat and cooled using a continuous flow cryocooler (CRYO Industries) fed with helium gas (99.9997% purity, Air Products). For steady-state PL spectroscopy, the backscattered PL emission was collected and dispersed using a 600 g mm^{-1} spectrometer (Princeton Instruments). For TRPL spectroscopy, the backscattered PL emission was collected and dispersed using a 600 g mm^{-1} spectrometer (Princeton Instruments) and temporally resolved using an Optronis streak camera system ($\sim 10 \text{ ps}$ resolution).

Steady-state absorption spectroscopy

The UV-Vis absorption spectrum was collected using a Shimadzu UV3600 spectrophotometer. The sample absorbance is scanned from 280 nm to 900 nm with 1 nm interval. The reference absorbance spectrum for the quartz substrate is also collected to correct for any contributions from it.

X-ray photoelectron spectroscopy (XPS)

XPS was performed using a home-built UHV multi-chamber system with a base pressure of at least 1×10^{-9} Torr ($\sim 10^{-7}$ Pa). The perovskite is grown on an indium tin oxide substrate and excited using a photon energy of 1486.7 eV. The X-ray photons originate from a monochromatic Al K_α source while the ejected photoelectrons are measured using an Omicron EA125 electron analyzer.

X-ray diffraction (XRD) spectroscopy

XRD was performed to identify the structural and phase properties of the PEPI thin film. The XRD pattern was recorded using a Bruker AXS (D8 ADVANCE) X-ray diffractometer using a Cu K_α radiation source with 2θ from 0° to 90° .

Results and discussion

Power dependent PL characterization

The structure of PEPI consists of alternating organic ($\text{C}_6\text{H}_5\text{C}_2\text{H}_4\text{NH}_3^+$) and inorganic layers (PbI_6^{4-} octahedron),

forming quantum wells that strongly confine excitons in the inorganic part – Fig. 1a. The self-assembled layered structure, which can be easily obtained *via* spin coating, is confirmed using XRD (see Fig. S3a, ESI†). The spin coated film is also shown to possess good substrate coverage and sample morphology (see Fig. S3b, ESI†). A strong excitonic absorption peak, arising from dielectric confinement in PEPI, can be seen in the steady-state absorption spectrum. The strong excitonic behavior also results in a large exciton binding energy of ~ 180 meV (see Fig. S3c, ESI†). Correspondingly, a strong excitonic emission peak (peak 1: ~ 525 nm) could be observed at room temperature

in the PL spectrum – Fig. 1b. The room temperature laser fluence dependent PL spectrum clearly shows the absence of ASE in PEPI, even at high laser fluence. In the low temperature regime (*i.e.*, 10 K), where the ASE threshold is expected to be lower, ASE is still not observed and only three spontaneous emission peaks are observed (peaks 1 and 2: ~ 535 nm and peak 3: ~ 545 nm) – Fig. 1c. Although peak 3 becomes more intense with increasing laser fluence, no superlinear increase in PL intensity (characteristic of ASE) could be observed. In both room temperature and low temperature PL measurements, the measurements were stopped at laser fluence just below the damage threshold. Here, the damage threshold using 400 nm excitation is of the order of $100 \mu\text{J cm}^{-2}$ or 10^{19} cm^{-3} incident photon density, beyond which the sample is damaged irrevocably and the PL emission diminishes (see Fig. S4, ESI†). These studies demonstrate and affirm the difficulties in obtaining ASE from PEPI at both room- and low-temperatures.

PL peak assignments

Prior to modeling the recombination kinetics in PEPI, we need to establish the identities of peaks 1, 2 and 3 (see Fig. 1c). The identity of peak 1 is well established to originate from free exciton recombination. The energy of peak 1 remains almost unchanged with a slight unconventional red shift with decreasing temperature – Fig. 2a. The red-shifting behavior, which has previously been observed in 3D perovskite, can be attributed to effects from the negative Varshni parameter.²³ Unfortunately, the origins of peaks 2 and 3 are still a matter of debate in the literature.

For peak 2, its origin was attributed to either a phonon replica or bound excitons. Gauthron *et al.*²⁴ observed two low temperature PL peaks (peak 1 and peak X (2.337 eV or 530.5 nm, which is not observed by us)) and found a significant interaction between the free excitons (peak 1) and optical phonons from their phenomenological model. From the established relation between peak 1 and peak X, they attributed peak X to be a phonon replica of peak 1. Peak X (at 530.5 nm) observed by Gauthron *et al.* at 10 K need not correspond to peak 2 (535 nm) in our study. Furthermore, peak X also lacks the characteristic features of phonon replicas. On the other hand, Hong *et al.*²⁵ observed multiple evenly spaced peaks (phonon replicas) at 2 K that are red-shifted from peak 1. However, Kitazawa *et al.*²⁶ attributed a bound exciton origin to peak 2. They found a large characteristic exciton binding energy (~ 200 meV) for $(\text{C}_6\text{H}_5\text{C}_2\text{H}_4\text{NH}_3)_2\text{PbI}_4$ as well as a much smaller binding energy of ~ 10 meV, which they attributed to the trapping–detrapping energy for bound excitons. This small energy is equivalent to a temperature of ~ 120 K and corresponds well to the temperature at which peak 2 becomes prominent. These latter findings are consistent with our observations – Fig. 2b and c. In addition, the decay rates for peaks 1 and 2 (Fig. 2d) are different and this suggests that peak 2 is unlikely to be a phonon replica of peak 1. The bound exciton origin for this red-shifted peak was also evident in a similar 2-D perovskite $((\text{C}_{10}\text{H}_{21}\text{NH}_3)_2\text{PbI}_4)$.²⁷ Next, significant quenching of peak 2 at low temperatures (77 K and 10 K – see Fig. S5a and b, ESI†) is

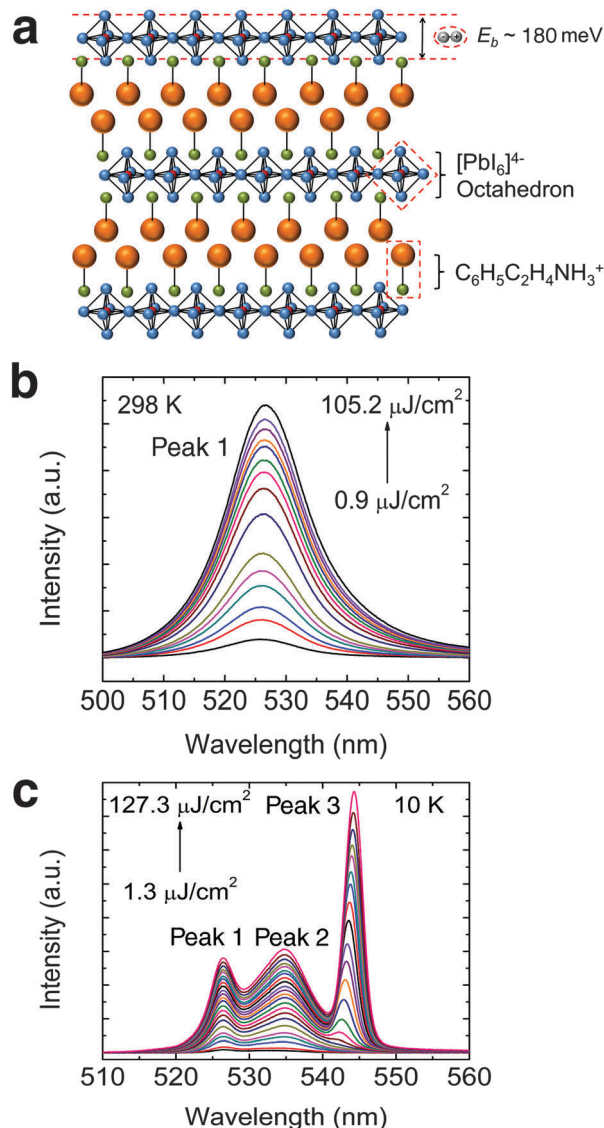

Fig. 1 Absence of ASE in PEPI. (a) Schematic structure of PEPI, which consists of alternating organic $\text{C}_6\text{H}_5\text{C}_2\text{H}_4\text{NH}_3^+$ and inorganic $[\text{PbI}_6]^{4-}$ layers. The naturally formed quantum well structure enables the formation of tightly bound excitons with binding energy (E_b) ~ 180 meV in the inorganic layers. (b) Room temperature pump fluence dependent PL spectrum of PEPI. (c) 10 K pump fluence dependent PL spectrum of PEPI showing three distinct emission peaks (peaks 1, 2 and 3). There is no superlinear increase in PL intensity for both temperatures. These optical experiments were conducted using 400 nm wavelength pump pulses (50 fs, 1 KHz).

Fig. 2 Low temperature bound exciton formation in PEPI. (a) Temperature dependent PL spectrum of PEPI showing two distinct emission peaks (peaks 1 and 2). (b) Integrated PL intensity at different temperatures for peak 1 and peak 2. The plot is fitted with a biexponential Arrhenius equation:

$$I = \frac{I_0}{1 + A_1 \exp\left(-\frac{E_1}{k_B T}\right) + A_2 \exp\left(-\frac{E_2}{k_B T}\right)}$$

Here, I is the integrated PL intensity, I_0 is the integrated PL intensity at 0 K, A_1 and A_2 are the amplitudes,

E_1 and E_2 are the activation energies, k_B is the Boltzmann constant and T is the temperature. The larger energy (E_1) is consistent with the exciton binding energy in PEPI. (c) Integrated PL intensity at different temperatures for peak 2. The small activation extracted with a single exponential Arrhenius equation is consistent with E_1 in (b). (d) Lifetime of peak 1 and 2 emission. These optical experiments were conducted using 400 nm wavelength pump pulses (50 fs, 1 KHz, $2.6 \mu\text{J cm}^{-2}$ (steady-state PL) or $7.0 \mu\text{J cm}^{-2}$ (time-resolved PL)).

also observed after depositing a layer of PMMA on top of PEPI. The variable degrees of surface quenching for different sample batches at 77 K (see Fig. S5b, ESI†) suggest large surface trapping contribution to peak 2 with some bulk trapping contribution – implying the significant presence of surface bound excitons. The passivation of surface trapping on PEPI by PMMA is consistent with the broadening of peak 1 (*i.e.*, free exciton peak), a PL intensity increase by $\sim 37\%$ and free exciton lifetime lengthening at ~ 10 K (see Fig. S5a, c and d, respectively, ESI†). X-ray photoelectron spectroscopy (XPS) revealed the presence of organic surface vacancies in PEPI (see Fig. S6 and Table S1, ESI†), which may be responsible for the surface trapping in PEPI. These findings suggest that surface trapping in PEPI cannot be neglected and could potentially have an adverse effect on the optical gain.

For peak 3 that appears at high excitation fluence, Shimizu *et al.* attributed the emission to originate from tri-excitons based on the 2.5 proportionality relation^{28,29} between the emission intensity and the excitation fluence. However, based on the quadratic increase in peak 3 emission with laser fluence at low temperatures, our result suggests a biexcitonic origin to peak 3 (see Fig. S7, ESI†). Such biexcitonic emission has also been previously reported for $(\text{C}_6\text{H}_{13}\text{NH}_3)_2\text{PbI}_4$.¹⁷

The biexcitons in PEPI, with a binding energy of 40 meV (see the ESI† for biexciton binding energy determination), more likely reside at the surface as bound biexcitons since peak 3 is suppressed with significant quenching of peak 2 (see Fig. S8, ESI†).

In summary, our findings show that peak 1 originates from free excitons, peak 2 arises from surface bound excitons, and peak 3 from surface bound biexcitons.

Theoretical modeling of charge carrier relaxation

To investigate the factors affecting ASE in PEPI, we developed a model for carrier and emission dynamics in PEPI. This model is modified based on a well-established model of ASE in semiconductor nanostructures to account for our peak assignment.³⁰ A schematic of the model is shown in Fig. 3a below, which comprises three emissive levels: free exciton, bound exciton and bound biexciton levels. This model involves the following relaxation processes following carrier excitation to the free carrier band $|C\rangle$: (1) formation of free excitons $|X\rangle$ and bound excitons $|X_B\rangle$, (2) capture of free excitons from bound excitons, (3) non-radiative relaxation of free and bound excitons, (4) emission of free excitons, (5) emission of bound excitons, (6) formation and emission of

Fig. 3 Rate equation analysis of energetics and kinetics from PEPI. (a) Proposed schematics of the exciton (open circles) relaxation channels in PEPI. (b) 10 K TRPL kinetics of peak 1 emission from PEPI. The kinetics is well modeled using a set of rate equations described in eqn (1)–(6). Inset: 2D time-wavelength image of the PL emission with peak 1 labeled. The optical experiments were conducted using 400 nm wavelength pump pulses (50 fs, 1 KHz, $7 \mu\text{J cm}^{-2}$). (c) Integrated PL intensity of the deconvolved peaks as a function of laser intensity extracted from Fig. 1c. The points are well-fitted using the proposed rate equations. Inset: Integrated PL intensity modeled at higher laser fluence with a predicted biexciton ASE threshold of 1.4 mJ cm^{-2} .

bound biexcitons $|XX_B\rangle$ and (7) non-radiative exciton–exciton annihilation. These processes are illustrated in Fig. 3a. From this model, the dynamics of the system are described by the following rate equations:

$$\frac{N_C}{dt} = +\frac{\alpha F}{\tau_L \sqrt{\pi} \hbar \omega} \exp\left(-\frac{t^2}{\tau_L^2}\right) - \frac{N_C}{\tau_{CX}} - \frac{N_C}{\tau_{CX_B}} + \frac{1}{2} \gamma (N_X^2 + N_{X_B}^2) \quad (1)$$

$$\frac{N_X}{dt} = +\frac{N_C}{\tau_{CX}} - k_{Xnr} N_X - \frac{N_X}{\tau_{Xr}} - v_{gX} g_X S_X - C_X N_X - \gamma N_X^2 \quad (2)$$

$$\frac{N_{X_B}}{dt} = +\frac{N_C}{\tau_{CX_B}} + C_X N_X - k_{X_Bnr} N_{X_B} - \frac{N_{X_B}}{\tau_{X_Br}} - v_{gX_B} g_{X_B} S_{X_B} - \gamma N_{X_B}^2 - \frac{B_{XX_B} N_{X_B}^2}{\tau_{XX_Br}} - v_{gXX_B} g_{XX_B} S_{XX_B} \quad (3)$$

$$\frac{S_X}{dt} = +v_{gX} g_X S_X + \frac{N_X}{\tau_{Xr}} \quad (4)$$

$$\frac{S_{X_B}}{dt} = +v_{gX_B} g_{X_B} S_{X_B} + \frac{N_{X_B}}{\tau_{X_Br}} \quad (5)$$

$$\frac{S_{XX_B}}{dt} = +v_{gXX_B} g_{XX_B} S_{XX_B} + \frac{B_{XX_B} N_{X_B}^2}{\tau_{XX_Br}} \quad (6)$$

The descriptions of the terms in eqn (1)–(6) are listed in Table 1. Meanwhile, the optical gain (g) is modeled by the competition between the absorption and the stimulated emission:

$$g_X = g_{X0}(2N_X/D_X - 1) \quad (7)$$

$$g_{X_B} = g_{X_B0}(2N_{X_B}/D_{X_B} - 1) \quad (8)$$

$$g_{XX_B} = g_{XX_B0}(2B_{XX_B}N_{X_B}^2/D_X - 1) \quad (9)$$

Here, the initial gain *i.e.*, g_{X0} , g_{X_B0} and g_{XX_B0} used are obtained from the linear absorption coefficient measurements, since gain = –absorption when $N = 0$. The density of states D_X is estimated by the density of valence electrons of the lead cation, which is the main contributor for the valence states. The parameters used in this model are either taken from experimental parameters or obtained from experimental data (see Table S2, ESI†, for the parameters). The free exciton lifetime (peak 1) from the pristine PEPI film can be well-fitted with the numerical solution of eqn (3) – Fig. 4b. We also found that the numerical solution of eqn (1)–(3) as a function of laser pump fluence can be well-fitted by the deconvolved PL integrated intensity for the respective peaks – Fig. 3c. Our model also predicts an absence of ASE in the pump fluence range used in our studies – consistent with our experimental data. The behavior

Table 1 Description of the terms used in eqn (1)–(6)

| Parameter | Description |
|----------------|---|
| $\hbar\omega$ | Pump photon energy. |
| α | Absorption coefficient at pump energy. |
| τ_{Xr} | Exciton radiative lifetime. |
| k_{Xnr} | Exciton non-radiative relaxation rate. |
| τ_{X_Bnr} | Bound exciton non-radiative relaxation rate. |
| k_{X_Bnr} | Bound biexciton non-radiative relaxation rate. |
| τ_{XX_Br} | Bound biexciton radiative relaxation rate. |
| τ_{CX} | Free carrier to exciton relaxation time |
| τ_{CX_B} | Free carrier to bound exciton relaxation time |
| τ_L | Laser time constant |
| C_X | Bound exciton trapping |
| B_{XX_B} | Bound biexciton formation coefficient |
| γ | Exciton–exciton annihilation coefficient |
| v_{gX} | Group velocity at exciton emission energy |
| v_{gX_B} | Group velocity at bound exciton emission energy |
| v_{gXX_B} | Group velocity at bound biexciton emission energy |

Fig. 4 Proposed strategies to promote optical gain. (a) Embedding 2D perovskite in a cavity (e.g. distributed Bragg reflector and distributed feedback cavity). Promoting single exciton gain using type II configuration by (b) surrounding 2D perovskite nanocrystals with a suitable semiconductor shell or (c) choosing an appropriate small bandgap organic constituent. (d) Employing a $(\text{H}_3\text{N}-\text{R}-\text{NH}_3)\text{PbI}_4$ structure to improve film morphology which in turn may reduce trapping.

of the respective peaks is also extrapolated to the regime above the damage threshold (above the laser fluence range used) – Fig. 3c inset. Our model predicts an ASE onset for peak 3 at a laser fluence of 1.4 mJ cm^{-2} originating from biexcitonic ASE in PEPI. This value is approximately 1 order of magnitude higher than the experimental damage threshold. Here, we also explored the possibility of single excitonic gain.³¹ While the single excitonic gain in caesium lead halide perovskite QDs⁹ and in CdSe-based³² colloidal quantum dots have previously been proposed, such single excitonic ASE onsets are not experimentally observed for peak 1 (free exciton) and peak 2 (bound exciton) in the PEPI system. This is understandable from the model that the dominant competing relaxation channels in PEPI (*i.e.*, free exciton to bound exciton relaxation and bound exciton to bound biexciton relaxation) would not favor the formation of metastable states. These competing channels are pre-requisites for the bound biexciton formation and for the subsequent bound biexciton gain build-up. Such competing channels are also not representative of a four-level lasing system found in excitonic organic semiconductor gain media.²²

Proposed solutions to overcome the optical gain challenges

While AlInGaP and GaN materials have made electrically pumped red and blue lasers possible, a suitable candidate for green lasers is still elusive.¹⁹ Thus, overcoming the green gap in lasing still remains an important research area. If a suitable candidate is found, this could mean a huge breakthrough in

the photonics industry. Conventional green lasing generated by frequency-doubling using a nonlinear crystal could then be replaced by a more efficient, directly generated green laser. In addition, high quality red, green and blue laser-based displays³³ could also be made possible. Solution processed 2D perovskite systems exhibiting strong optically and electrically pumped spontaneous green emission could possibly contribute to the realization of electrically pumped green laser. However, achieving optical gain with these 2D materials has proven challenging. From the literature reports and our experimental results, we propose several key factors that may help to overcome the optical gain problem in 2D perovskites.

Managing exciton recombination losses is an important factor for achieving optical gain in 2D perovskites. From PL measurements, we establish that there is significant surface trapping in PEPI. The surface trapping gives rise to the formation of bound excitons (from free excitons) and bound biexcitons (from bound excitons). These competing pathways could be one of the reasons behind the lack of optical gain from biexcitons (formed directly by free excitons). As shown from our theoretical model, only bound biexcitonic gain can be achieved from this system. Unfortunately, this also means that these competing relaxation channels present cannot be eliminated for bound biexciton formation. These channels could cause losses and account for the calculated high bound biexcitonic ASE threshold of 1.4 mJ cm^{-2} . A possible way to reduce loss and lower the ASE/lasing threshold would be to introduce an ultrahigh quality laser cavity (see Fig. 4a).

Enhancing excitonic gain through the use of 2D perovskite nanocrystals to induce optical gain could also be explored. Typical nanocrystal gain involves at least two excitons (biexciton), but the formation of biexcitons at high laser fluence can promote non-radiative Auger recombination. Klimov *et al.*³¹ had previously proposed a type-II core/shell configuration which employs the carrier-induced Stark effect to induce single exciton gain and eliminate Auger recombination. The carrier-induced Stark effect breaks the symmetry between absorption and emission by confining opposite charges in the core and the shell, respectively, thereby making the population inversion of single excitons possible. Similarly, a semiconductor shell surrounding 2D perovskite nanocrystals (core) can be used (see Fig. 4b). Building on this idea and with a careful choice of the organic component (R), a 2D perovskite thin film with type II electronic configuration³⁴ could also be fabricated (see Fig. 4c) and may be useful for achieving single exciton gain. From our XPS data, the defects in PEPI were found to be from C and N deficiencies that could possibly originate from C–N bond breakage in the organic compound. Therefore using an organic component with a larger C–N bond dissociation energy may be helpful for reduction in trapping. Instead of using a (R–NH₃)PbI₄ structure where van der Waals forces exist between two ammonium units, a covalently bonded ammonium unit structure with the formula (NH₃–R–NH₃)PbI₄³⁴ (see Fig. 4d) would be helpful. Strong covalently bonded constituents could lead to a better film morphology which can result in a further reduction in trapping.³⁵

Conclusion

In retrospect, ultrafast spectroscopy provides a powerful means to probe exciton relaxation in PEPI. Regardless of excitation at low temperature or room temperature, no ASE could be observed in spin-coated PEPI thin films. Formation and relaxation of free excitons, bound excitons and biexcitons were found to be very dependent on each other. Theoretical modeling revealed a high bound biexciton ASE threshold beyond the damage threshold of PEPI, with no optical gain predicted from free and bound excitons. Several recommendations have also been proposed. A combination of these suggestions may be needed to overcome the optical gain challenge in 2D perovskites.
