Frame, metric and geodesic evolution in shape-changing nematic shells

Cyrus Mostajeran,^a Mark Warner^{b*} and Carl D. Modes^{c,d}

Non-uniform director fields in flat, responsive, glassy nematic sheets lead to the induction of shells with non-trivial topography on the application of light or heat. Contraction along the director causes metric change, with, in general, the induction of Gaussian curvature, that drives the topography change. We describe the metric change, the evolution of the director field, and the transformation of reference state material curves, e.g. spirals into radii, as curvature develops. The non-isometric deformations associated with heat or light change the geodesics of the surface, intriguingly even in regions where no Gaussian curvature results.

1 Introduction

Nematic solids elongate or contract along their preferred direction, the director \mathbf{n} , in response to heat, light, pH change, and solvent uptake. In the two directions perpendicular to \mathbf{n} there is an attendant contraction or elongation, either conserving volume (elastomers) or not (glasses), except where the driver is solvent exchange (elastomers) where there must be volume change.

Although deformations are simple locally, if the director field $\mathbf{n}(\mathbf{r})$ is non-uniform in the plane of a sheet-like sample, it will in general be driven to develop Gaussian curvature (GC) to avoid expensive distortion from the new, natural contracted/elongated state. There is a strong motive to have non-uniform fields and thus switchable Gaussian Curvature, since such systems offer new forms of strong actuation where blocking evolution to the new natural state allows one to harness the attendant stretches; see for instance Ware *et al.*¹

The induced Gaussian curvature can be specified in terms of the new metric tensor, $\mathbf{a} = \mathbf{U}^T \cdot \mathbf{U}$ (with \mathbf{U} the deformation gradient to a new relaxed state arising from the stimulations listed above). The metric specifies the changed intrinsic lengths in the surface and the GC can be expressed in terms of the spatial variation of \mathbf{a} , that is, through the connection coefficients $\mathbf{\Gamma}$.

The local thermo-optical deformation gradients are simple and based on \mathbf{n}

$$\mathbf{U} = \lambda \mathbf{n} \otimes \mathbf{n} + \lambda^{-\nu} \mathbf{m} \otimes \mathbf{m} \quad (1)$$

where \mathbf{m} is the direction in-plane that is perpendicular to \mathbf{n} , that is, the in-plane orthogonal dual of \mathbf{n} . There is a contraction $\lambda < 1$ along \mathbf{n} and elongation of $\lambda^{-\nu}$ along \mathbf{m} . The constant $\nu \geq \frac{1}{2}$ has been termed the opto-thermal Poisson ratio² in analogy with the conventional Poisson ratio; it determines the response perpendicular to a deformation induced along \mathbf{n} .

The in-plane pattern for $\mathbf{n}(\mathbf{r})$ and $\mathbf{m}(\mathbf{r})$ is set at the time of sample preparation. It can evolve under the action of \mathbf{U} : where \mathbf{n} is non-uniform, there may additionally be local rotations $\mathbf{R}(\mathbf{r})$ in order that the total deformation $\mathbf{F} = \mathbf{R} \cdot \mathbf{U}$ remains locally and globally compatible, assuming that the surface that evolves is embeddable and smooth *etc.* The local rotations of the material convect \mathbf{n} and \mathbf{m} to new values that constitute a new, diagonal frame on which to base the next deformation and subsequent further rotation. The metric induced is of course unchanged by the rotations: $\mathbf{a} = \mathbf{F}^T \cdot \mathbf{F} = \mathbf{U}^T \cdot \mathbf{R}^T \cdot \mathbf{R} \cdot \mathbf{U} = \mathbf{U}^T \cdot \mathbf{U}$.

We investigate 3 critical aspects of these non-uniform deformations:

(1) The metric of the space evolves as λ changes. After every increment of λ and hence of \mathbf{a} , should subsequent development use the incremented \mathbf{a} , or can one jump directly to a finite deformation λ , and simply take the metric that corresponds to that \mathbf{F} ? We find that one can – the metric is not “dragged”. Equally, we will show that the rotations induced can be simply compounded, even when the λ s are large. We show this property by a general argument based on a pair of successive finite deformations.

(2) In circularly symmetric systems of general theoretical and experimental interest, it is clear that there are deformation-induced rotations of material directions, but that circles centred at the origin must transform into circles. We offer an explicit geometric construction that resolves these two apparently contradictory aspects, and recover expressions for the rotations involved and for the inflation of the intrinsic circles that define the system. We show

how certain general curves, proto-radii, become geodesic radii on distortion. We further put conditions on the director field that is needed to generate only shells of revolution, and thereby give a criterion for when circular symmetry breaks down.

(3) We consider geodesics on cones that result from the response of circular, radial or, in general, logarithmic spiral director distributions. They are different from those of cones that are more conventionally constructed from flat sheets. The former are the products of non-isometric transformations. The curves in the flat space that are geodesics in the target space differ, even though both types of cones have zero Gaussian curvature, except at their tips.

2 Metric evolution and the compounding of their intermediate states

We consider the evolution of the induced metric upon heating of a sheet-like nematic sample with director field $\mathbf{n}(\mathbf{r})$. The heating of the sample manifests as a gradually decreasing $\lambda < 1$, indicating further contractions along the director. As the system evolves, both \mathbf{n} and \mathbf{m} can locally rotate with respect to material lines across the surface of the sample. We analyse this evolution by discretising it into a 2-step process: an initial deformation Φ_{λ_1} corresponding to a contraction by λ_1 along \mathbf{n} and mapping an initial surface Σ_0 onto an intermediate surface Σ_1 , followed by a second deformation Φ_{λ/λ_1} corresponding to a contraction by λ/λ_1 along the new evolved director field which maps Σ_1 onto a final surface Σ_2 , as depicted in Fig. 1.

Consider a mesh of curves \mathcal{C}_1 and \mathcal{C}_2 on a surface, initially planar. In calculations of surface evolution, especially of circular symmetry, these might typically be circles and either radii or radially advancing spirals. One derives from these curves the corresponding family of tangents \mathbf{t}_1 and \mathbf{t}_2 . In the above examples mentioned, they are $(\dot{r}_1, \dot{\theta}_1)$ with $\dot{r}_1 = 0$ for circles (where $\cdot = d/ds$ and s is a unit speed parametrisation), and $(\dot{r}_2, \dot{\theta}_2)$ – the tangent to a spiral curve of interest, for instance to a proto-radius. The original tangents, \mathbf{t}_i , transform into new ones, $\tilde{\mathbf{t}}_i$, for $i = 1, 2$, as

$$\mathbf{F}_{\lambda_1} \cdot \mathbf{t}_i \equiv \mathbf{R}_{\lambda_1} \cdot \mathbf{U}_{\lambda_1} \cdot \mathbf{t}_i \equiv \tilde{\mathbf{t}}_i \quad (2)$$

Fig. 1 Compatibility of local deformations. The director field \mathbf{n} and its in-plane orthogonal dual \mathbf{m} remain orthogonal throughout the evolution as they locally rotate with respect to material lines across the surface. Finite deformations compound as expected.

where the rotation \mathbf{R}_{λ_1} is with respect to the given collection of frames on the evolving surfaces. \mathbf{R}_{λ_1} is induced by the deformation and its action on \mathbf{n} gives $\tilde{\mathbf{n}} = \mathbf{R}_{\lambda_1} \cdot \mathbf{n}$. Both \mathbf{R} and \mathbf{n} depend on \mathbf{r} , and likewise $\tilde{\mathbf{m}} = \mathbf{R}_{\lambda_1} \cdot \mathbf{m}$. We will see below the total deformation naturally broken down (its polar decomposition) into a $\mathbf{R}_{\lambda_1} \cdot \mathbf{U}_{\lambda_1}$ since \mathbf{U}_{λ_1} is delivered diagonal in its \mathbf{n}, \mathbf{m} frame. The rotation we determine below convects \mathbf{n} and \mathbf{m} and provides us with a new frame where, by construction, the subsequent \mathbf{U} is diagonal.

This subsequent deformation $\mathbf{U}_{\lambda/\lambda_1}(\tilde{\mathbf{n}})$ now occurs, by a further factor λ/λ_1 which is along the current director $\tilde{\mathbf{n}}$ rather than the original \mathbf{n} . The current mesh $\tilde{\mathcal{C}}_i$ will further deform. We will need, for instance, directional relationships between further deformed meshes using the metric $\mathbf{a}_{\lambda/\lambda_1}(\tilde{\mathbf{n}}) = \mathbf{U}_{\lambda/\lambda_1}^T \cdot \mathbf{U}_{\lambda/\lambda_1}$ resulting from the further deformation λ/λ_1 along the current director $\tilde{\mathbf{n}}$:

$$\tilde{\mathbf{t}}_2^T \cdot \mathbf{a}_{\lambda/\lambda_1}(\tilde{\mathbf{n}}) \cdot \tilde{\mathbf{t}}_1. \quad (3)$$

For instance if (3) = 0, then the initial mesh of curves \mathcal{C}_1 and \mathcal{C}_2 have evolved under two, compounded deformations into normal coordinates. We need to be reassured, here by explicit construction, that the evolution of the metric, so central to these calculations, is being correctly accounted for during successive deformations where it too is evolving.

One can re-write eqn (3):

$$\mathbf{t}_2^T \cdot \mathbf{U}_{\lambda_1}^T \cdot \mathbf{R}_{\lambda_1}^T \cdot \left((\lambda/\lambda_1)^2 \tilde{\mathbf{n}} \otimes \tilde{\mathbf{n}} + (\lambda/\lambda_1)^{-2\nu} \tilde{\mathbf{m}} \otimes \tilde{\mathbf{m}} \right) \cdot \mathbf{R}_{\lambda_1} \cdot \mathbf{U}_{\lambda_1} \cdot \mathbf{t}_1. \quad (4)$$

Now one can see how the intermediate state after deformation λ_1 is immaterial: $\mathbf{R}_{\lambda_1}^T$ and \mathbf{R}_{λ_1} act (forward and backward respectively) on the $\tilde{\mathbf{n}}$ and $\tilde{\mathbf{m}}$ to restore them to \mathbf{n} and \mathbf{m} respectively. Recall that \mathbf{F}_{λ_1} is based on \mathbf{n} and \mathbf{m} , as is now the central part of eqn (4) since it has become $(\lambda/\lambda_1)^2 \mathbf{n} \otimes \mathbf{n} + (\lambda/\lambda_1)^{-2\nu} \mathbf{m} \otimes \mathbf{m}$. Then the \mathbf{F} and \mathbf{F}^T can be contracted with the central part to give $(\lambda^2 \mathbf{n} \otimes \mathbf{n} + \lambda^{-2\nu} \mathbf{m} \otimes \mathbf{m}) \equiv \mathbf{a}_\lambda(\mathbf{n})$, with the result

$$\mathbf{t}_2^T \cdot \mathbf{a}_\lambda(\mathbf{n}) \cdot \mathbf{t}_1. \quad (5)$$

We have thus shown that, although the metric evolves as the directors are convected by deformations, it is sufficient to consider even a non-linear deformation to be in terms of the initial state and the metric appropriate to any large deformations based on the initial state. That is, the frame is “dragged” but not to any fundamental effect. Conversely, the compounding of infinitesimal deformations and rotations to give, say, the compounding of two large deformations rules out any higher order differential effects in the metric evolution.

It should be noted that a global deformation map $\Phi: \Sigma_i \rightarrow \Sigma_f$, from an initial surface Σ_i to a final surface Σ_f , carries by contrast much more information than is provided by the metric formalism and isometric embedding approach taken in Mostajeran,³ for instance. An analysis based purely on the metric formalism typically yields the surface that is formed following the stimulation of a given director field by solving an isometric embedding problem based on the induced metric, but it does not specify where individual points from the initial surface end up on the final surface. Generally, it is difficult to

determine such a global deformation even when the final surface has been identified. However, in Section 3 we provide a detailed picture of the movement of individual points during the course of the deformation for the important class of circularly symmetric director patterns, which typically result in surfaces of revolution. One needs to consider trajectories and their length changes, as in ref. 5. We use such methods to give a prescription in Section 5 for when a circularly symmetric director field $\mathbf{n}(\mathbf{r})$ will give a surface of revolution, rather than a ruffled surface.

3 Circular symmetry and the rotations attendant on deformations

Circularly symmetric director patterns, generically spirals, generate deformations based on local frames of \mathbf{n} and \mathbf{m} . The director fields themselves will evolve, which we now examine, unless they were the special cases of radii and circumferences. By symmetry, deformations must take circles to circles, albeit in general inflated or deflated. At a point (r, θ) the director has an angle $\alpha(r)$ with the radial direction, $\hat{\mathbf{r}}$; see Fig. 2(a). This angle varies with radius except for the special case of logarithmic spirals of \mathbf{n} , where $\alpha = \text{constant}$ and nematic contractions yield simple cones.^{2,4}

Consider, Fig. 2(b), in a frame based on \mathbf{n} and \mathbf{m} , depicting a contraction by λ along \mathbf{n} . It fans out away from \mathbf{n} the in-material vectors \mathbf{t} and $\hat{\mathbf{r}}$ to $U_\lambda \cdot \mathbf{t}$ and $U_\lambda \cdot \hat{\mathbf{r}}$ (no longer unit vectors); the angle γ between $U_\lambda \cdot \mathbf{t}$ and \mathbf{t} is defined in the figure. Thus

$$U_\lambda(\mathbf{n}(\mathbf{r})) \cdot \mathbf{t} = p\mathbf{R}_\gamma \cdot \mathbf{t}, \quad (6)$$

with p the degree of circumferential deflation/inflation, and \mathbf{R}_γ a rotation by γ . Since points on circles remain on circles, then clearly the action from neighbouring points gives a local angular convection to restore $U_\lambda \cdot \mathbf{t}$ to tangency, in general along with a rotation of the circle as a whole, so the point at θ evolves to θ' ; see Fig. 2(c). The next section gives explicit forms for $\theta' - \theta$ by considering how special curves (“proto-radii”) in the reference state evolve to be actual radii in the target state.

Fig. 2 (a) A section of a circle (dotted) in the initial (flat) space before distortion, showing its tangent \mathbf{t} . The director $\mathbf{n}(\mathbf{r})$ is at angle $\alpha(r)$ to the radial direction, $\hat{\mathbf{r}}$. (b) A contraction by a factor λ along \mathbf{n} rotates (and distorts) general vectors, e.g. \mathbf{t} and $\hat{\mathbf{r}}$, towards the perpendicular \mathbf{m} . For instance, the tangent \mathbf{t} was rotated through angle γ . (c) By symmetry, circles must transform overall into circles (here shown as deflated). Through a rotation $\mathbf{R}_{-\gamma}$, the vector $\mathbf{F}_\lambda \cdot \mathbf{t}$ is restored to tangency and the director, \mathbf{n}' , is now at angle $\alpha - \gamma$ to the radial direction. In general, material points \mathbf{r} rotate to a new angle θ' . In the text we delay discussing the extra rotation, and mark the restored tangent simply as \mathbf{t} .

The angle between $U_\lambda \cdot \mathbf{t}$ and \mathbf{n} became $\pi/2 - \alpha + \gamma$ after deformation. As $U_\lambda \cdot \mathbf{t}$ (with all other in-material vectors) is rotated by $-\gamma$ to make it again a tangent (with rescaling to restore it to being a unit vector), then the current director \mathbf{n}' is now at an angle $\alpha - \gamma$ to the new radial direction. Note that this latter, radial direction was not originally so, but evolved from its pre-image (the proto radius) to be a radius.

Expanding out eqn (6) in the original frame to get the fanning out, one has:

$$\lambda(\mathbf{n}(\mathbf{r}) \cdot \mathbf{t})\mathbf{n} + \lambda^{-\nu}(\mathbf{m}(\mathbf{r}) \cdot \mathbf{t})\mathbf{m} = p\mathbf{R}_\gamma \cdot \mathbf{t}. \quad (7)$$

The projections of \mathbf{t} onto \mathbf{n} and \mathbf{m} were respectively s_α and $-c_\alpha$ (with $s \equiv \sin$, $c \equiv \cos$). Multiplying both sides by $\mathbf{R}_{-\gamma}$, the vectors \mathbf{n} and \mathbf{m} become $\mathbf{n}' = \mathbf{R}_{-\gamma} \cdot \mathbf{n}$ and $\mathbf{m}' = \mathbf{R}_{-\gamma} \cdot \mathbf{m}$; see Fig. 2(c), but for the moment delay considering the rotation by $\theta' - \theta$ so the restored tangent in Fig. 2(c) is denoted by the original \mathbf{t} :

$$\lambda s_\alpha \mathbf{n}' - \lambda^{-\nu} c_\alpha \mathbf{m}' = p\mathbf{t}. \quad (8)$$

Contracting this equation with the unit tangent \mathbf{t} and with the unit radial vectors gives respectively:

$$\lambda s_\alpha s_{\alpha-\gamma} + \lambda^{-\nu} c_\alpha c_{\alpha-\gamma} = p \quad (9)$$

$$\lambda s_\alpha c_{\alpha-\gamma} - \lambda^{-\nu} c_\alpha s_{\alpha-\gamma} = 0. \quad (10)$$

The latter relation gives the new director angle, which can be injected into the former expression for $p(r)$ to give the inflation. In summary

$$t_{\alpha-\gamma} = \lambda^{1+\nu} t_\alpha \quad (11)$$

or

$$\cot \gamma = (b^2 + \lambda^{2\nu}) / (b(1 - \lambda^{1+\nu})) \quad (12)$$

$$p(r) = \lambda^{-\nu} \sqrt{c_{\alpha(r)}^2 + \lambda^{2(1+\nu)} s_{\alpha(r)}^2}, \quad (13)$$

where $b = \cot \alpha$. The inflation depends on radius according to the initial director angle $\alpha(r)$ to the radial direction, and depends on the deformation. Of special interest is the location of $r_1(\lambda)$ where $p = 1$, for there the circumference is unchanging and the evolved shell can be anchored to an unchanging circumferential support without strain-mismatch. At that condition, one has $s_{\alpha_1} = \sqrt{\frac{1 - \lambda^{2\nu}}{1 - \lambda^{2(1+\nu)}}}$ which can be solved then for $r_1(\lambda)$. This result shows that the anchoring condition (3.16) of Mostajeran *et al.*⁵ is completely general and not simply for logarithmic spiral systems.

Rotations can be seen explicitly to compound, as they do *via* metric considerations:

$$\begin{aligned} \tan(\alpha - \delta) &= \left(\frac{\lambda}{\lambda_1}\right)^{1+\nu} \tan(\alpha - (\delta - \gamma)) \\ &= \left(\frac{\lambda}{\lambda_1}\right)^{1+\nu} \lambda_1^{1+\nu} \tan(\alpha) = \lambda^{1+\nu} \tan(\alpha) \end{aligned} \quad (14)$$

where λ_1 takes the system from $\alpha \rightarrow \alpha - (\delta - \gamma)$, and then λ/λ_1 from $\alpha - (\delta - \gamma)$ to $\alpha - \delta$, that is a further γ . Intermediate steps, λ_1 with angular advancement $(\delta - \gamma)$, are seen to be inessential.

Fig. 4 A circularly symmetric shell with an in-material radius of length $l_1(r)$ extending from the pole (dot) to the current shell edge (dot), where the circumference is $l_2(r)$. Recall that the current radius has evolved from a pre-image (proto-radius) in the reference state extending from the centre of a spiral director field out to an r . An addition dl_1 to the in-material radius leads to an increased circumference $l_2 + dl_2$.

we are dealing with length changes in the θ -direction. Taking its derivative and taking the above condition for circular symmetry one obtains:

$$2\lambda^{1-\nu}r > da_{\theta\theta}/dr$$

$$2\lambda^{1+\nu} > 2 - 2\left(1 - \lambda^{2(1+\nu)}\right) \sin^2 \alpha - \left(1 - \lambda^{2(1+\nu)}\right)r \sin(2\alpha) \frac{d\alpha}{dr}. \quad (21)$$

One can immediately recover the condition⁴ separating cones and anti-cones for log spirals $\mathbf{n}(\mathbf{r})$ where $\alpha = \text{const.}$, and also recover the condition on the tuning parameter c for the $\alpha(r)$ generating spherical spindles and hyperbolic cones.⁵ For instance, for a constant $K > 0$ the director field

$$\alpha(r) = \frac{1}{2} \arccos \left(-\frac{Kr^2}{2(\lambda^{-2} - \lambda^{2\nu})} + c \right) \quad (22)$$

introduced in ref. 5 defines a spiral nematic pattern which encodes constant Gaussian curvature $K > 0$ on the domain on which (22) is defined. The parameter c is a tuning parameter that can be used to adjust the radius on which the pattern is defined. The metric component $a_{\theta\theta}$ for the director field (22) takes the form

$$a_{\theta\theta} = \frac{r^2}{2} \left(\lambda^{-2\nu} + \lambda^2 + c(\lambda^{-2\nu} - \lambda^2) - \frac{1}{2} \lambda^{2-2\nu} K r^2 \right), \quad (23)$$

and upon substitution into (21) yields

$$\lambda^{2-2\nu} K r^2 + 2\lambda^{1-\nu} - \lambda^{-2\nu} - \lambda^2 - c(\lambda^{-2\nu} - \lambda^2) > 0, \quad (24)$$

which must be satisfied for all values of $r > 0$ in the domain of $\alpha(r)$ to result in a surface of revolution. This is clearly the case if and only if (24) is satisfied at $r = 0$. That is, precisely if

$$c < \frac{2\lambda^{1-\nu} - \lambda^{-2\nu} - \lambda^2}{\lambda^{-2\nu} - \lambda^2} = 1 - \frac{2}{1 + \lambda^{1+\nu}}, \quad (25)$$

which is in agreement with the condition⁵ on c for a spherical spindle of constant positive curvature K to result from the director field specified by (22).

6 Evolution of geodesics

Considering how points on a nematic surface move as the surface evolves under heating leads to an interesting observation concerning geodesics on the surface. Specifically, that material lines that form geodesics on an initial surface will generally not remain geodesics as the surface evolves. This is certainly to be expected when the induced metric is non-Euclidean, since in such cases the intrinsic geometry of the resulting surface is different. The more remarkable result is that a geodesic material line may not remain a geodesic under evolution even in cases where the induced metric is flat, *i.e.* does not generate Gaussian curvature.

We highlight this feature through a simple example involving the formation of cones from an initially flat surface by 2 different methods. In the first method, we simply cut out a sector from a circular disc and join the new edges of the remaining surface to form a cone by bending, as shown in Fig. 5. This is possible since a cone has zero Gaussian curvature at every point except for its tip, and thus away from this singular point has the same intrinsic geometry (Euclidean) as the plane by Minding's theorem. In this method, geodesics in the initially flat disc will map onto geodesics on the resulting cone. The second method is based on heating an initially flat nematic disc patterned by an azimuthal director field, which will form a cone with opening angle $\phi = \sin^{-1}(\lambda^{1+\nu})$ as explained in ref. 4.

Now for a given metric $ds^2 = a_{\alpha\beta} dx^\alpha dx^\beta$, the geodesics satisfy the Euler-Lagrange equations of the functional

$$I[x] = \int L(x, \dot{x}) dt = \int a_{\alpha\beta}(x) \dot{x}^\alpha \dot{x}^\beta dt. \quad (26)$$

For the standard Euclidean metric $ds^2 = dx^2 + dy^2 = dr^2 + r^2 d\theta^2$, the Euler-Lagrange equations in polar coordinates are

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{r}} = \frac{\partial L}{\partial r} \Rightarrow 2\ddot{r} = 2r\dot{\theta}^2 \quad (27)$$

$$\frac{d}{dt} \frac{\partial L}{\partial \dot{\theta}} = \frac{\partial L}{\partial \theta} \Rightarrow r^2 \ddot{\theta} = C \quad (28)$$

where C is a constant. Thus, the straight line geodesics in polar coordinates arise as solutions to the system

$$\begin{cases} r^2 \dot{\theta} = C, \\ \ddot{r} = C^2/r^3. \end{cases} \quad (29)$$

Fig. 5 Forming a cone by bending a flat circular disc with a missing sector. Straight lines on the disc map to geodesics on the cone.

On heating the azimuthal pattern, the induced metric becomes $ds^2 = \lambda^{-2\nu} dr^2 + \lambda^2 r^2 d\theta^2$ and the Lagrangian in (26) is modified to $L(r, \theta, \dot{r}, \dot{\theta}) = \lambda^{-2\nu} \dot{r}^2 + \lambda^2 r^2 \dot{\theta}^2$. The geodesic equations now take the form

$$\begin{cases} r^2 \dot{\theta} = C, \\ \ddot{r} = \lambda^{2(1+\nu)} C^2 / r^3. \end{cases} \quad (30)$$

The solutions to this system are curves on the initial disc that become geodesics on the resulting cone. Clearly, we see that the systems in (29) and (30) are distinct and generally give rise to different solutions unless $C = 0$. That is, straight lines on the flat disc will generally not map onto geodesics on the resulting cone, even where no Gaussian curvature is induced in the process. Indeed we have also seen, in the log spiral variant of the evolution to cones, that a resultant geodesic in the form of a radial line originates as a log spiral in the reference state which is definitely not an initial geodesic.

7 Discussion

The evolution of the shape of a nematic surface upon stimulation is governed by the metric induced by local deformations encoded by the director field. The stimulation of the sample is not instantaneous, but is achieved through a continuous process such as heating, during which the surface undergoes a continuous family of deformations. The director field itself also evolves during this process and undergoes local rotations with respect to material lines across the evolving surface. Due to the anisotropic nature of nematic surfaces, the question of compatibility of infinitesimal deformations within the metric framework is a non-trivial one that needs to be considered. In this work, we have addressed this concern and demonstrated that the evolution of the surface and director field is indeed consistent with such a framework. It should be noted that this issue does not arise for materials which undergo local expansion/contraction in a conformal or isothermal manner in response to stimulus, such as responsive hydrogels,⁶ since there is no

potential “frame-dragging” effect in such materials. Furthermore, while it is possible to express a metric associated with a nematic director field in isothermal form through a suitable change of coordinates,⁷ the necessary coordinate transformation is dependent on λ and hence is not valid throughout the evolution. By considering the local rotations of the director field during the evolution of the deformation of a nematic surface, we also obtain a description of how individual material points move on the evolving surface for the class of circularly symmetric director fields which form surfaces of revolution.
