# CO<sub>2</sub> photoreduction on mixed Ti/Zr-MOF-525: bicarbonate as the active intermediate and the role of Ti substitution

Thanyaporn Puengpoka,<sup>a</sup> Jirapat Santatiwongchai,<sup>b</sup> Warot Chotpatiwetchkul,<sup>\*a</sup> Sareeya Bureekaew,<sup>c</sup> Muhammad Saleh,<sup>d</sup> Anchalee Junkaew<sup>b</sup> and Sarawoot Impeng<sup>b</sup>

The photocatalytic reduction of CO<sub>2</sub> in metal–organic frameworks (MOFs) offers a sustainable route to C<sub>1</sub> fuels and chemicals. Herein, density functional theory (DFT) calculations elucidate CO<sub>2</sub> reduction on mixed Ti/Zr-MOF-525 clusters bearing missing linker defects, modeled by Zr<sub>6</sub>, Ti<sub>1</sub>Zr<sub>5</sub>, and Ti<sub>2</sub>Zr<sub>4</sub> clusters. Two distinct mechanistic pathways are identified: the OH-passive and OH-assisted routes. In the passive case, CO<sub>2</sub> binds weakly at a coordinatively unsaturated Ti/Zr site and undergoes direct hydrogenation to CO and HCOOH, with desorption being thermodynamically preferred over further hydrogenation. In contrast, the OH-assisted pathway proceeds via a bicarbonate-mediated mechanism, where surface –OH attacks adsorbed CO<sub>2</sub> to form node-bound \*HCO<sub>3</sub>. This step is both thermodynamically favorable and kinetically accessible ( $\Delta G^\ddagger < 0.5$  eV). Subsequent proton–electron additions convert \*HCO<sub>3</sub> to \*OCHO and H<sub>2</sub>O, favored by ~1 eV over competing routes. These findings identify \*HCO<sub>3</sub> as the true reactive precursor and reveal that Ti substitution promotes deeper hydrogenation beyond two-electron products, enhancing CH<sub>4</sub> formation on the Ti<sub>2</sub>Zr<sub>4</sub> cluster. Overall, the results highlight the importance of node composition and surface hydroxyl groups in porphyrinic MOFs for optimizing multi-electron CO<sub>2</sub> reduction and controlling product selectivity by tailoring the metal node environments.

## Introduction

Carbon dioxide (CO<sub>2</sub>) is a major greenhouse gas driving global warming and climate change. Reducing CO<sub>2</sub> emissions is thus an urgent challenge on the path toward achieving carbon neutrality. Carbon capture and utilization (CCU) has emerged as a promising strategy because it simultaneously lowers atmospheric CO<sub>2</sub> levels and upcycles this abundant C<sub>1</sub> feedstock into valuable chemicals and fuels, such as carbon monoxide (CO), formic acid (HCOOH), methanol (CH<sub>3</sub>OH), and methane (CH<sub>4</sub>).<sup>1–4</sup> CO<sub>2</sub> can be converted via thermocatalysis, electrocatalysis, photocatalysis, and photoelectrochemical or biochemical pathways.<sup>4</sup> Among these, photocatalytic CO<sub>2</sub> reduction is particularly

attractive because it directly harnesses solar energy under mild operating conditions, providing a sustainable route to close the carbon cycle and produce renewable fuels.<sup>5,6</sup>

A wide range of photocatalysts have been explored for solar-driven CO<sub>2</sub> conversion, including molecular complexes, noble-metal nanoparticles, organic polymers, inorganic semiconductors, and hybrid materials.<sup>6,7</sup> However, these systems often suffer from limited stability, modest selectivity, and inefficient charge separation, highlighting the need for improved photocatalyst design. Metal–organic frameworks (MOFs) have emerged as a versatile class of photocatalysts for CO<sub>2</sub> reduction.<sup>6,8,9</sup> Their high surface areas, tunable porosity, adjustable chemical composition, and engineerable electronic structures make them well-suited for light-driven catalysis. From the fundamentals of CO<sub>2</sub> photocatalysis, an efficient photocatalyst should combine (i) strong absorption in the visible-light region (bandgap  $\leq 3$  eV), (ii) long-lived excited states, (iii) efficient charge generation and separation, (iv) high charge mobility, and (v) strong CO<sub>2</sub> adsorption capacity.<sup>2,5,6</sup> MOFs are uniquely positioned to integrate these features within a single material, placing them among the most promising candidates for next-generation photocatalyst design. Within this family, porphyrinic MOFs are especially compelling because their strong visible-light absorption and well-defined, modular

catalytic environments directly address these fundamental requirements for efficient CO<sub>2</sub> photoreduction.<sup>10,11</sup>

Within this subclass, particular attention has been paid to Zr-porphyrinic frameworks such as MOF-525 and MOF-545, which have emerged as especially promising candidates. Both structures consist of tetrakis(4-carboxyphenyl)porphyrin (TCPP) linkers connected to Zr<sub>6</sub>-oxo clusters, but they commonly exhibit distinct product selectivity: MOF-525 tends to yield CO and CH<sub>4</sub>, whereas MOF-545 more often favors formate.<sup>12,13</sup> Their photocatalytic performance can be further enhanced through porphyrin metalation or partial Ti<sup>4+</sup> substitution at the Zr<sub>6</sub> node.<sup>14–16</sup> In MOF-525, Ti incorporation can enhance charge separation and enable partial reduction of Ti<sup>4+</sup> to Ti<sup>3+</sup> under light irradiation, generating electron-rich sites that stabilize key intermediates and promote deeper hydrogenation toward CH<sub>4</sub>.<sup>16</sup> Crucially, catalytic activity is governed by the availability of open metal sites (OMS); increasing their density and accessibility enhances CO<sub>2</sub> adsorption and subsequent conversion, thereby enhancing overall catalytic performance. In this regard, hydroxyl-capped missing-linker defects increase the density and accessibility of Zr/Ti OMS, which serve as active sites that (i) directly bind and activate CO<sub>2</sub> for stepwise hydrogenation or (ii) facilitate nucleophilic attack by neighboring surface OH groups on adsorbed CO<sub>2</sub> to form carbonate-like intermediates. Similar Zr<sup>3+</sup>-OH frustrated Lewis pairs (FLPs) have been identified as active sites for CO<sub>2</sub> activation in UiO-66,<sup>17</sup> suggesting analogous behavior in porphyrinic MOFs. In addition, spectroscopic and computational studies have shown that photoexcitation of the porphyrin linker can induce linker-to-node charge transfer to the inorganic node, the catalytic center.<sup>12,16,18,19</sup> Collectively, the interplay between node composition, defect chemistry (*via* OMS and FLPs), and linker-node charge transfer collectively dictates the reaction mechanism and product selectivity in photocatalytic CO<sub>2</sub> reduction.

Despite these advances, the mechanistic roles of Ti substitution and surface -OH groups at defect sites in controlling product selectivity remain insufficiently understood. Herein, density functional theory (DFT) calculations are employed to investigate CO<sub>2</sub> photoreduction on mixed Ti/Zr-MOF-525 clusters bearing missing linker defects. Finite-cluster models containing missing-linker defects capped by -OH/H<sub>2</sub>O ligands are constructed to represent catalytically relevant environments. Two mechanistic pathways are examined: an OH-passive pathway, in which hydroxyl groups act as spectators, and an OH-assisted pathway, where hydroxyl groups directly attack the adsorbed CO<sub>2</sub> to form carbonate-like intermediates that promote subsequent hydrogenation steps. By systematically comparing Zr<sub>6</sub>, Ti<sub>1</sub>Zr<sub>5</sub>, and Ti<sub>2</sub>Zr<sub>4</sub> clusters, we map the free-energy landscape to reveal how Ti substitution and hydroxyl defects modulate reaction energetics and product selectivity, providing mechanistic design guidelines for efficient MOF-based photocatalysts.

## Computational details

We employed a finite-cluster model to study CO<sub>2</sub> photoreduction on mixed Ti/Zr-MOF-525 containing missing-linker defects.

The Zr<sub>6</sub>-oxo cluster was extracted from the experimental MOF-525 crystal structure.<sup>20</sup> One tetrakis(4-carboxyphenyl)porphyrin (TCPP) linker was removed to create a missing-linker defect, resulting in undercoordinated Zr centers. These sites were initially capped with hydroxyl (-OH) and water (H<sub>2</sub>O) ligands to restore coordination and maintain charge neutrality. To generate the catalytically active site, one H<sub>2</sub>O ligand was then removed, creating an open (coordinatively unsaturated) metal center at Zr or Ti (for substituted clusters). The remaining porphyrin linkers were truncated and capped with acetate groups, following our previous protocol,<sup>21,22</sup> which preserves the local electronic structure of the node and adsorption energetics in cluster models. Ti substitution was introduced at the defect-centered node by replacing one or two Zr atoms, yielding three catalyst models denoted as Zr<sub>6</sub>, Ti<sub>1</sub>Zr<sub>5</sub>, and Ti<sub>2</sub>Zr<sub>4</sub>-MOF-525, respectively. These clusters allow a direct evaluation of the role of Ti substitution on product selectivity and the participation of hydroxyl groups in the reaction mechanism. The constructed cluster models are shown in Fig. 1.

Spin-unrestricted DFT calculations were performed with the M06-L functional<sup>23</sup> using Gaussian 16.<sup>24</sup> Stuttgart–Dresden (SDD) effective core potentials with associated basis sets were applied to Zr and Ti,<sup>25</sup> while the def2-SVP basis set was used for C, H, and O during geometry optimizations.<sup>26</sup> Single-point energy refinements were carried out with the def2-TZVP basis set on non-metal atoms, including Grimme's D3 dispersion correction<sup>27</sup> and the SMD implicit solvation model<sup>28</sup> (water as solvent) to account for long-range dispersion and solvent stabilization effects. During optimization, the carboxylate carbon atoms of acetate caps were constrained, whereas all other atoms were fully relaxed.

Harmonic frequency calculations at the M06-L/def2-SVP level provided zero-point and thermal corrections. Low-frequency vibrational modes were treated using a Truhlar-type quasi-harmonic correction<sup>29</sup> implemented in the GoodVibes program,<sup>30</sup> applying a 100 cm<sup>-1</sup> cutoff and a vibrational scaling factor of 0.976 for thermochemical analysis. All reported energies are Gibbs free

Fig. 1 Structural representation of MOF-525: (a) pristine framework, (b) cluster model with -OH/H<sub>2</sub>O capping at a missing linker defect, and (c) mixed Ti/Zr-MOF-525 showing Ti substitution at the metal node and the formation of Zr/Ti open sites upon H<sub>2</sub>O removal. Zr, Ti, O, N, C and H atoms are shown in cyan, gray, red, blue, dark gray and white, respectively.

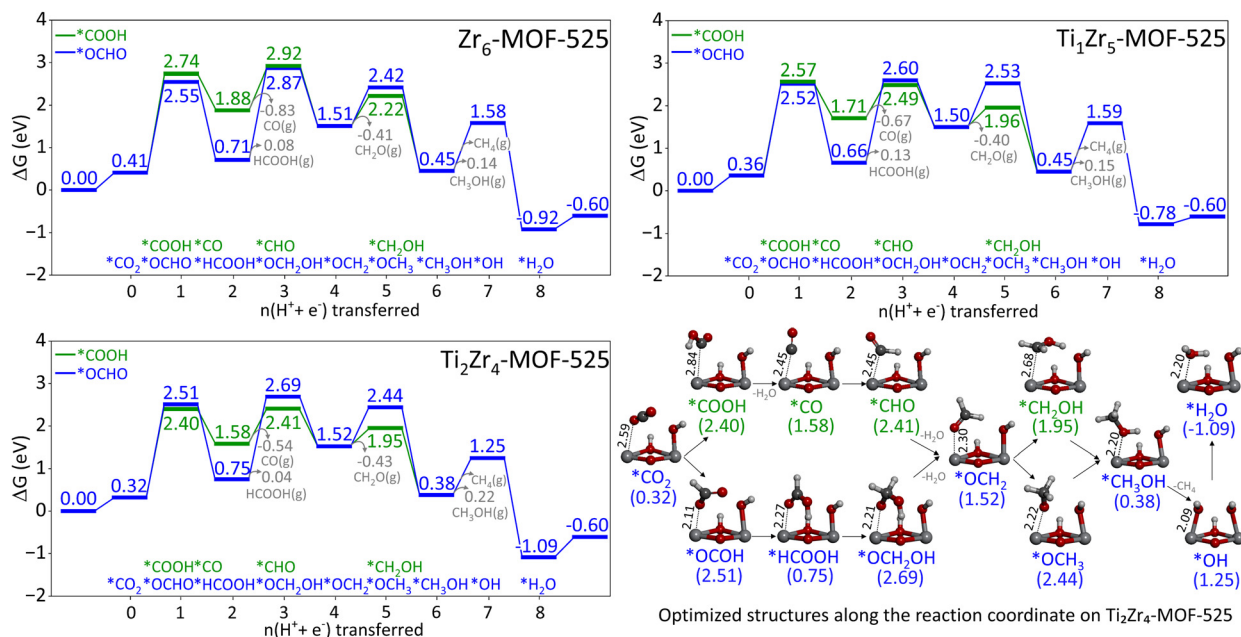

Fig. 2 Gibbs free-energy profiles ( $\Delta G$ , eV) for the OH-passive pathway on  $Zr_6$ -,  $Ti_1Zr_5$ -, and  $Ti_2Zr_4$ -MOF-525 clusters. The reactant state (MOF +  $CO_2$ ) is used as the energy reference, and water desorption regenerates the active site. Optimized structures along the reaction coordinate are shown for the  $Ti_2Zr_4$ -MOF-525, while those for  $Zr_6$ - and  $Ti_1Zr_5$ -MOF-525 are provided in the SI.

restricts charge transfer to  $CO_2$  and hinders its reduction. Under photocatalytic conditions, partial reduction of the node metal to  $Zr^{3+}/Ti^{3+}$  could promote electron donation to  $CO_2$  and facilitate activation; however, our neutral state results describe the intrinsic thermodynamic character of OH-passive sites prior to photoinduced charge transfer.

Hydrogenation of  $*COOH$  produces  $*CO$ , completing the two-electron reduction sequence. For  $*CO$ , two protonation channels were examined, formation of  $*CHO$  or  $*COH$ . The  $*CHO$  intermediate is more stable by  $> 1$  eV than  $*COH$  (Table S1), whereas  $*COH$  is intrinsically unstable and reacts with a neighboring surface  $-OH$  to give a  $C(OH)_2$ -like species (Fig. S1). Thus,  $*COH$  cannot exist as an isolated intermediate under OH-passive conditions. All such high-energy or spontaneously reacting species are depicted in gray in Fig. S1 and Table S1 to indicate their minor mechanistic relevance.

Hydrogenation of  $*OCHO$ , in contrast, yields  $*HCOOH$ , which is thermodynamically more stable than  $*CHO$  for all catalysts. Further protonation converts  $*HCOOH$  to  $*OCH_2OH$  and subsequent hydrogenation of either  $*OCH_2OH$  or  $*CHO$  produces  $*OCH_2$  (Fig. 2).

Both formate and carboxyl pathways therefore merge at  $OCH_2$ , a common precursor to  $CH_3OH$  and  $CH_4$ .

However, desorption of the  $C_1$  products  $CO$  and  $HCOOH$  is thermodynamically more favorable than continued hydrogenation. The computed free energies of  $CO$  desorption are  $-0.83$ ,  $-0.67$ , and  $-0.54$  eV for  $Zr_6$ ,  $Ti_1Zr_5$ , and  $Ti_2Zr_4$  clusters, respectively, indicating that  $CO$  is already released from the surfaces.  $HCOOH$  desorption is slightly endergonic ( $\sim 0.1$  eV, suggesting that it can also desorb under mild conditions). Because both  $CO$  and  $HCOOH$  desorption are preferred over additional hydrogenation, the  $CO_2$

reduction process on OH-passive nodes terminates at these two-electron products. This result emphasizes that, in the absence of surface-OH participation, reduction at Zr/Ti sites is confined to  $CO$  and  $HCOOH$  formation, underscoring the necessity of local reactivity  $-OH$  environments for achieving deeper multi-proton-electron conversions.

Experimentally, deeper hydrogenation to  $CH_4$  has been observed for mixed Ti/Zr-MOF-525 catalysts,<sup>16</sup> likely due to photoinduced charge transfer and active OH sites that enhance  $CO_2$  activation and promote multi-electron processes. The following section therefore examines the OH-assisted pathway, where surface hydroxyl groups directly engage in  $CO_2$  activation.

### OH-assisted pathway

As in the passive pathway,  $CO_2$  first adsorbs at a coordinatively unsaturated Zr/Ti site. In contrast, the OH-assisted mechanism involves the direct participation of the surface  $-OH$ , which attacks the adsorbed  $CO_2$  carbon to form a node-bound bicarbonate ( $*HCO_3$ ) species. This step represents a Lewis acid-base activation, where the surface  $-OH$  acts as a Lewis base and the Zr/Ti site as a Lewis acid. No proton-electron transfer occurs at this stage; the actual reduction begins only after  $*HCO_3$  formation.

Fig. 3 presents the calculated Gibbs free-energy profiles for  $CO_2$  photoreduction on  $Zr_6$ -,  $Ti_1Zr_5$ -, and  $Ti_2Zr_4$ -MOF-525 clusters, together with their optimized structures along the reaction pathway (Fig. S2). All high-energy intermediates are shown in gray in Fig. S2 and listed in Table S2 to indicate their minor mechanistic significance. At the transition state, the OH approaches the  $CO_2$  carbon, forming a partial  $O_{(OH)}-C$  bond, elongating both C-O bonds, and bending the O-C-O angle further from linearity. The transition state exhibits single imaginary frequencies of 166.2i,

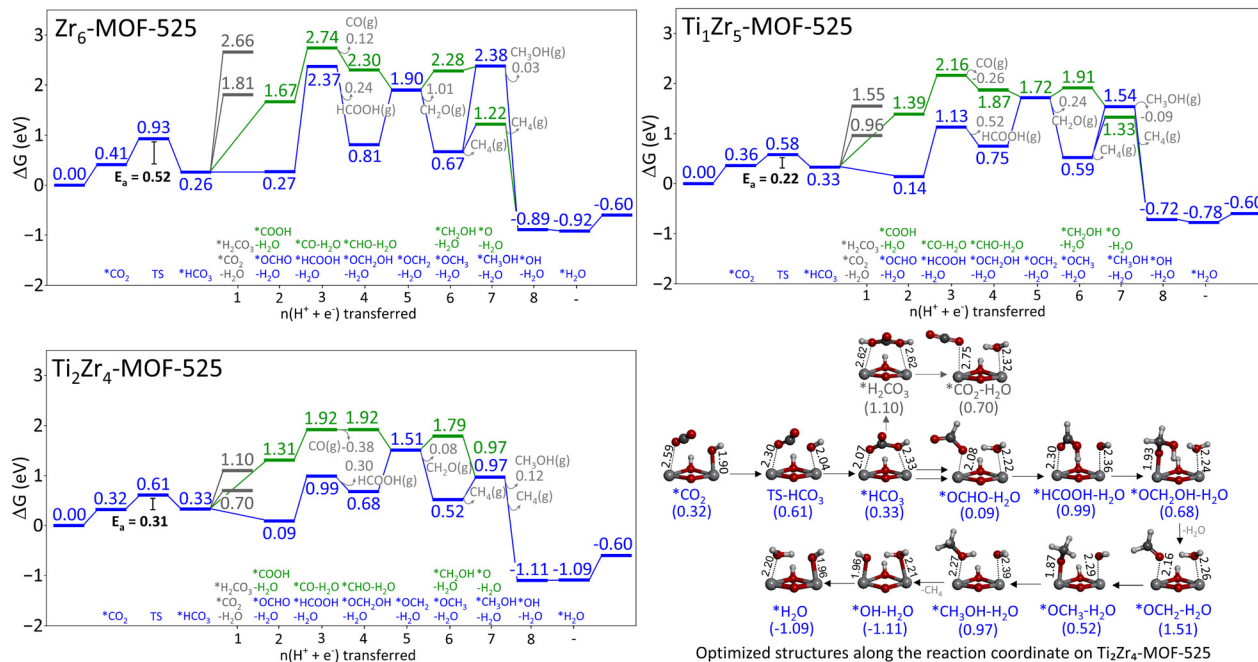

Fig. 3 Gibbs free-energy profile ( $\Delta G$ , eV) for the OH-assisted pathway on  $Zr_6$ -,  $Ti_1Zr_5$ -, and  $Ti_2Zr_4$ -MOF-525 clusters. The reactant state (MOF +  $CO_2$ ) is used as the energy reference, and water desorption regenerates the active site. Optimized structures along the reaction coordinate are shown for  $Ti_2Zr_4$ -MOF-525, while those for  $Zr_6$ - and  $Ti_1Zr_5$ -MOF-525 are provided in the SI.

269.4i, and 295.5i  $cm^{-1}$  for  $Zr_6$ ,  $Ti_1Zr_5$ , and  $Ti_2Zr_4$ , respectively. The reaction is slightly endergonic ( $\sim 0.3$  eV) with activation free energies of 0.52, 0.22, and 0.31 eV for  $Zr_6$ ,  $Ti_1Zr_5$ , and  $Ti_2Zr_4$ , respectively, demonstrating that Ti substitution markedly lowers the OH-attack barrier.

Charge and structural analyses clarify this effect (Table 1). In the  $Zr_6$  system, charge accumulation resides on the metal ( $\Delta q(M) = -0.14|e|$ ) with negligible  $O \rightarrow C$  ( $\sim 0|e|$ ), yielding a moderately bent  $CO_2$  ( $O-C-O = 155.8^\circ$ ) and a long  $O_{(OH)}-C$  distance (2.04 Å), consistent with the highest activation barrier (0.52 eV). In  $Ti_1Zr_5$ , a slight positive shift in  $\Delta q(M)$  (+0.01|e|) indicates Ti-induced polarization of the  $Zr-OH$  site, enabling limited donation into  $CO_2$   $\pi^*$  orbitals. Consequently,  $CO_2$  bends more ( $149.5^\circ$ ) and the  $O_{(OH)}-C$  distance shortens (1.87 Å), reducing the activation free energy to 0.22 eV.

Table 1 Charge redistribution, activation Gibbs free energy ( $\Delta G^\ddagger$ ), and  $CO_2$  geometry along the OH-assisted pathway.  $\Delta q = q(TS) - q(ADS)$ ;  $\Delta q$  in |e|;  $\Delta G^\ddagger$  in eV;  $O-C-O$  in degrees

System	$\Delta q_{C(CO_2)}$  e	$\Delta q_{O(OH)}$  e	$\Delta q_M$  e	$\Delta q(O \rightarrow C)$  e	$\Delta G^\ddagger$ (eV)	$O-C-O$ ( $^\circ$ )
$Zr_6$	+0.004	+0.009	-0.143	0.000	0.52	155.8
$Ti_1Zr_5$	+0.044	+0.024	+0.010	0.000	0.21	149.5
$Ti_2Zr_4$	+0.045	-0.030	+0.012	+0.030	0.30	150.4

Note:  $\Delta q$  values were obtained from Mulliken charge analysis, where  $\Delta q = q(TS) - q(ADS)$ . The adsorption state (ADS) and the transition state (TS) correspond to the OH-assisted pathway. Positive  $\Delta q_{C(CO_2)}$  denotes charge accepted by the  $CO_2$  carbon, while negative  $\Delta q_{O(OH)}$  indicates electron donation from the hydroxyl oxygen.  $\Delta q_M$  represents the change on the open  $Zr/Ti$  center; where a positive value indicates electron depletion and enhanced electrophilicity.  $\Delta q(O \rightarrow C)$  represents the donation magnitude ( $\geq 0$ ).

For  $Ti_2Zr_4$ , the  $-OH$  ligand binds directly to Ti, enhancing  $O \rightarrow C$  charge transfer (0.03|e|), shortening the  $Ti-O_{(OH)}$  to 2.04 Å (vs.  $> 2.15$  Å for  $Zr-O_{(OH)}$ ), and yielding a short  $O_{(OH)}-C$  distance (1.88 Å) that stabilizes the transition state ( $E_a = 0.31$  eV). Overall, Ti incorporation enhances metal-oxo polarization, strengthens  $OH \cdots CO_2$  interaction, and promotes facile  $CO_2$  activation.

After the transition state, node-bound bicarbonate ( $*HCO_3$ ) is formed with relative energies of 0.26, 0.33, and 0.33 eV for  $Zr_6$ ,  $Ti_1Zr_5$ , and  $Ti_2Zr_4$ , respectively. The subsequent hydrogenation of  $*HCO_3$  can proceed by (i) protonation at the oxygen atom to yield carbonic acid ( $*H_2CO_3$ ), which readily decomposes into  $*CO_2$  and  $H_2O$ , or (ii) carbon protonation to give  $*OCHO + H_2O$ . The newly formed species binds to the adjacent  $Zr/Ti-OH$  site and stabilizes the intermediates *via* hydrogen bonding. Our calculations show that the formate pathway is thermodynamically preferred:  $*OCHO$  is more stable than  $*H_2CO_3$  and ( $*CO_2 + H_2O$ ) by 2.40 (1.54), 1.41 (0.82), and 1.01 (0.61) eV for  $Zr_6$ ,  $Ti_1Zr_5$ , and  $Ti_2Zr_4$ , respectively. These results identify  $HCO_3$  as the true intermediate in  $CO_2$  activation, in line with previous reports on bicarbonate-mediated  $CO_2$  reduction over UiO-66 MOFs<sup>17</sup> and Fe-porphyrin catalysts.<sup>33,34</sup>

These two routes differ fundamentally in proton-electron requirements. Formation of  $*H_2CO_3$  involves one proton-electron pair and oxygen protonation without carbon reduction—a non-reductive acid-base step. Conversely,  $*OCHO + H_2O$  formation requires two proton-electron pairs and creates a C-H bond—the true first reduction of  $CO_2$ . This explains the lower free energies for the formate route and consistent thermodynamic preference across all nodes. Moreover, the  $HCO_3 \rightarrow OCHO$  conversion is slightly more exergonic for Ti-containing

nodes (by  $\geq 0.2$  eV), confirming that Ti enhances both kinetic and thermodynamic driving forces.

As shown in Fig. 3, the competing carboxyl route  $^*\text{COOH} + \text{H}_2\text{O}$  is  $> 1$  eV less favorable for all systems. Compared with the passive-pathway, the  $^*\text{COOH}$  intermediate in the OH-assisted mechanism is approximately 1 eV more stable (1.31 vs. 2.52 eV for  $\text{Ti}_2\text{Zr}_4$ ). Subsequent hydrogenation of  $^*\text{COOH}$  produces  $^*\text{CO}$  with relative energies of 2.74, 2.16, and 1.92 eV for  $\text{Zr}_6$ ,  $\text{Ti}_1\text{Zr}_5$ , and  $\text{Ti}_2\text{Zr}_4$ , respectively.

Given the reported band gaps of  $\sim 1.7$  eV for Zr-MOF-525 and mixed Ti/Zr-MOF-525 and 1.9 eV for free-base TCPP,<sup>16,35</sup> CO formation within  $\leq 2.0$  eV (for  $\text{Ti}_2\text{Zr}_4$ ) is thermodynamically accessible under visible-light excitation, whereas the  $\sim 2.5$  eV barrier in the passive pathway exceeds the available photoenergy. This correlation suggests that CO generation preferentially occurs *via* the OH-assisted route, especially in Ti-substituted systems. Subsequent hydrogenation of  $^*\text{CO}$  to  $^*\text{CHO}$  or  $^*\text{COH}$  on  $\text{Ti}_2\text{Zr}_4$  is less favorable than CO desorption, implying that CO is readily released once formed.

Following  $^*\text{OCHO}$  formation, two hydrogenation routes are possible: (i) attack at the carbon to produce  $^*\text{OCH}_2\text{O} \rightarrow ^*\text{OCH}_2\text{OH}$ , or (ii) attack at the oxygen to generate  $^*\text{HCOOH} \rightarrow ^*\text{CH}_2\text{OOH}$ . The  $^*\text{OCH}_2\text{OH}$  intermediate then reduces to  $^*\text{OCH}_2$  with  $\text{H}_2\text{O}$  release. Our calculations reveal that hydrogenation *via* oxygen is thermodynamically more favorable across all systems. The next protonation converts  $^*\text{OCH}_2$  to  $^*\text{OCH}_3$ , which is more stable than  $^*\text{CH}_2\text{OH}$ . Further protonation of  $^*\text{OCH}_3$  yields  $^*\text{CH}_3\text{OH}$  and continued hydrogenation leads to  $\text{CH}_4$  formation alongside surface O species that are finally re-hydroxylated, closing the catalytic cycle.

The  $^*\text{OCHO} \rightarrow ^*\text{HCOOH}$  conversion is identified as the potential-determining step, with calculated free-energy changes ( $\Delta G$ ) of 2.10, 0.99, and 0.90 eV for  $\text{Zr}_6$ ,  $\text{Ti}_1\text{Zr}_5$ , and  $\text{Ti}_2\text{Zr}_4$ , respectively (Fig. 3). The desorption energies of the  $\text{C}_1$  products were also evaluated and found to be higher than their subsequent hydrogenation energies. For  $\text{Ti}_2\text{Zr}_4$ ,  $^*\text{OCH}_2$  desorption (0.08 eV; relative energy 1.59 eV) is less favorable than its conversion to  $^*\text{OCH}_3$  (0.52 eV). Similarly,  $^*\text{CH}_3\text{OH}$  desorption (1.09 eV) is less stable than final  $\text{CH}_4$  formation accompanied by surface  $-\text{OH}$  regeneration. Overall, Ti substitution and active surface hydroxyls synergistically lower the activation barriers and stabilize key intermediates, thereby driving multi-electron  $\text{CO}_2$  reduction beyond the two-electron limit observed on OH-passive surfaces.

In summary,  $\text{CO}_2$  photoreduction on mixed Ti/Zr-MOF-525 proceeds most favorably through the OH-assisted formate pathway, where  $\text{CO}_2$  activation and the initial hydrogenation yield  $^*\text{OCHO}$  as the key intermediate. The subsequent multi-step hydrogenation follows the sequence  $^*\text{HCOOH} \rightarrow ^*\text{OCH}_2\text{OH} \rightarrow ^*\text{OCH}_2 \rightarrow ^*\text{OCH}_3 \rightarrow ^*\text{CH}_3\text{OH} \rightarrow ^*\text{OH}$ , accompanied by water formation and regeneration of surface  $-\text{OH}$  groups. For  $\text{Ti}_2\text{Zr}_4$ , the  $^*\text{OCH}_3 \rightarrow ^*\text{CH}_3\text{OH}$  and  $^*\text{OCH}_3 \rightarrow ^*\text{O} + \text{CH}_4$  steps are energetically comparable, allowing both  $\text{CH}_3\text{OH}$  and  $\text{CH}_4$  formation. In contrast, for  $\text{Zr}_6$  and  $\text{Ti}_1\text{Zr}_5$ ,  $^*\text{OCH}_3$  is more stable than  $^*\text{O}$ , making  $\text{CH}_4$  formation less favorable. Ti substitution enhances  $\text{CO}_2$  activation, stabilizes key intermediates, and

lowers the thermodynamic barriers for deep reduction. Cooperative interactions among open Zr/Ti sites, neighboring hydroxyl groups, and weakly adsorbed water molecules facilitate proton transfer and hydrogen-bond stabilization along the pathway. Overall, Ti-containing nodes exhibit the strongest driving force for multi-electron transfer, enabling selective  $\text{CH}_4$  formation under visible-light excitation.

To place the mechanistic results in the context of photocatalysis, we briefly examine the photophysical properties of the mixed Ti/Zr-MOF-525 frameworks. Periodic HSE06//PBE-D3(BJ) calculations yield band gaps of approximately 2.0 eV for all three systems, placing them within the visible-light region and in good agreement with the experimentally reported band gap of  $\sim 1.7$  eV for mixed Ti/Zr-MOF-525.<sup>16</sup> As shown by the density of states (DOS) analysis (Fig. S3, SI), the highest occupied crystal orbital (HOCO) and lowest unoccupied crystal orbital (LUCO) are largely dominated by porphyrin linker states, while Ti substitution introduces additional Ti 3d states closer to the LUCO, thereby enhancing the electron-accepting character of the metal-oxo node. Although light absorption and charge generation are governed by the extended periodic framework, the subsequent catalytic steps are controlled by the local coordination environment at defective Ti/Zr nodes; accordingly, the cluster-level analysis captures the ground-state energetics that dictate reaction pathways and product selectivity under photocatalytic conditions.

## Conclusions

Density functional theory calculations reveal that Ti substitution and node-associated hydroxyl groups jointly govern photocatalytic  $\text{CO}_2$  reduction on MOF-525 clusters. Two mechanistic routes were identified: an OH-passive pathway, where the surface  $-\text{OH}$  group remains inactive and  $\text{CO}_2$  reduction terminates at CO and HCOOH, and an OH-assisted pathway, in which a nearby  $-\text{OH}$  directly attacks the adsorbed  $\text{CO}_2$  to form a node-bound  $^*\text{HCO}_3$  intermediate. The  $^*\text{HCO}_3$  species acts as the true reactive precursor, undergoing thermodynamically favorable and kinetically accessible conversion to  $^*\text{OCHO}$  and subsequently to  $\text{CH}_4$ . Ti incorporation strengthens the OH- $\text{CO}_2$  coupling, lowers the activation barriers, and stabilizes intermediates, thereby facilitating deeper multi-electron hydrogenation. Overall, the cooperative effects of Ti substitution and surface hydroxyl groups provide key design guidelines for tuning MOF-525 toward selective  $\text{CH}_4$  formation *via* the OH-assisted, bicarbonate-mediated mechanism. These findings underscore the importance of tailoring node composition and surface hydroxyl groups in porphyrinic MOFs to optimize multi-electron  $\text{CO}_2$  reduction pathways and control product selectivity.
