## Enhancing $C_{\geq 2}$ product selectivity in electrochemical $CO_2$ reduction by controlling the microstructure of gas diffusion electrodes†

Francesco Bernasconi, <sup>ab</sup> Alessandro Senocrate, <sup>\*ac</sup> Peter Kraus <sup>a</sup> and Corsin Battaglia <sup>abc</sup>

We fabricate polymer-based gas diffusion electrodes with controllable microstructure for the electrochemical reduction of  $CO_2$ , by means of electrospinning and physical vapor deposition. We show that the microstructure of the electrospun substrate is affecting the selectivity of a Cu catalyst, steering it from  $H_2$  to  $C_2H_4$  and other multicarbon products. Specifically, we demonstrate that gas diffusion electrodes with small pores (e.g. mean pore size 0.2  $\mu m$ ) and strong hydrophobicity (e.g. water entry pressure  $>1$  bar) are necessary for achieving a remarkable faradaic efficiency of  $\sim 50\%$  for  $C_2H_4$  and  $\sim 75\%$  for  $C_{\geq 2}$  products in neutral 1M KCl electrolyte at 200  $mA\ cm^{-2}$ . We observe a gradual shift from  $C_2H_4$  to  $CH_4$  to  $H_2$  during long-term electrochemical reduction of  $CO_2$ , which we ascribe to hygroscopic carbonate precipitation in the gas diffusion electrode resulting in flooding of the Cu catalyst by the electrolyte. We demonstrate that even with minimal electrolyte overpressure of 50 mbar, gas diffusion electrodes with large pores (mean pore size 1.1  $\mu m$ ) lose selectivity to carbon products completely, suddenly, and irreversibly in favor of  $H_2$ . In contrast, we find that gas diffusion electrodes with small pore size (mean pore size 0.2  $\mu m$ ) and strong hydrophobicity (water entry pressure  $\sim 5$  bar) are capable of resisting up to 1 bar of electrolyte overpressure during  $CO_2RR$  without loss of selectivity. We rationalize these experimental results in the context of a double phase boundary reactivity, where an electrolyte layer covers the Cu catalyst and thus governs local  $CO_2$  availability. Our results emphasize the pivotal role of microstructure and hydrophobicity in promoting high  $C_{\geq 2}$  product selectivity and long-term stability in  $CO_2RR$  flow cells.

### Broader context

The electrochemical  $CO_2$  reduction reaction offers the unique possibility to power the conversion of  $CO_2$  with electricity from renewable energy technologies, which is a necessary condition to close the carbon loop. An important technological goal is to maximize the selectivity towards one single carbon product while avoiding the parasitic  $H_2$  evolution reaction, to avoid costly and energy-intensive separation methods. Amongst carbon products,  $C_2H_4$  is one of the most sought after, as it is a suitable platform chemical for the synthesis of long-chain hydrocarbons. Presently, Cu is the only known electrocatalyst capable of converting  $CO_2$  to  $C_2H_4$  at technological relevant current densities, albeit with limited selectivity. To improve the selectivity towards  $C_2H_4$  selectivity and suppress the  $H_2$  evolution reaction we purposefully modify the morphology of hydrophobic polymer-based gas diffusion electrodes made in-house by electrospinning. We find that gas diffusion electrodes substrates with small pore sizes and strong hydrophobicity grant high  $C_2H_4$  and  $C_{\geq 2}$  products selectivity ( $\sim 50\%$  and  $\sim 75\%$ , respectively) in neutral electrolyte, as well as resilience to electrolyte overpressures ( $>1$  bar) during  $CO_2RR$ . These findings highlight the potential of substrate control as a scalable strategy to improve the selectivity of the electrochemical  $CO_2$  reduction reaction.

## Introduction

The conversion of  $CO_2$  into sustainable fuels and chemicals has been identified as a key technology to achieve carbon neutrality by closing the carbon loop.<sup>1,2</sup> Converting  $CO_2$  electrochemically via the electrochemical  $CO_2$  reduction reaction ( $CO_2RR$ ) offers the unique possibility to power this conversion with electricity from renewable energy technologies.<sup>1</sup> Significant scientific

effort has been devoted to improving CO<sub>2</sub>RR activity and selectivity, as well as to understanding its mechanisms, starting from the studies of Hori, who pioneered the reduction of CO<sub>2</sub> dissolved in aqueous electrolytes in the 1980s.<sup>3–5</sup> More recent developments employ gas diffusion electrodes (GDEs) to circumvent CO<sub>2</sub> mass transport limitations to the catalyst resulting from the low solubility of CO<sub>2</sub> in water (35 mM at 25 °C),<sup>6</sup> enabling CO<sub>2</sub>RR at technologically relevant current densities  $\geq 200 \text{ mA cm}^{-2}$ .<sup>7,8</sup>

An important technological goal to avoid costly product separation is to achieve high selectivity towards one single carbon product, while suppressing the parasitic hydrogen evolution reaction (HER). However, depending on the catalyst material,<sup>9</sup> pH and composition of the electrolyte,<sup>5,10–17</sup> temperature,<sup>18,19</sup> pressure,<sup>20,21</sup> and GDE type,<sup>22–25</sup> the product selectivity of the CO<sub>2</sub>RR can vary significantly. For example Cu, the most studied catalyst for CO<sub>2</sub>RR, can produce both single carbon (CH<sub>4</sub>, CO and HCOOH, collectively labeled C<sub>1</sub>) and multicarbon products (*e.g.* C<sub>2</sub>H<sub>4</sub>, CH<sub>3</sub>CH<sub>2</sub>OH, *etc.*, collectively labeled C<sub>≥2</sub>), yielding a complex product distribution. Amongst multicarbon products, C<sub>2</sub>H<sub>4</sub> is particularly desirable as it can be used as a precursor to obtain long-chain hydrocarbons. An emerging strategy to enhance C<sub>2</sub>H<sub>4</sub> selectivity and suppress HER consists in controlling the local environment of the catalyst,<sup>23,24,26–28</sup> for example by creating an abrupt interface between a hydrophobic polymer substrate and a hydrophilic Cu catalyst yielding high C<sub>2</sub>H<sub>4</sub> selectivity in strongly basic electrolytes.<sup>29</sup>

In this work, we purposely control the pore size of hydrophobic polymer substrates made in-house by electrospinning. We find that Cu GDEs based on substrates with small pore size and strong hydrophobicity achieve high C<sub>2</sub>H<sub>4</sub> and C<sub>≥2</sub> products selectivity in neutral electrolyte as well as resilience to electrolyte overpressures (>1 bar) during CO<sub>2</sub>RR. Through mass transport considerations and the comparison between CO<sub>2</sub> and CO reduction experiments we provide evidence that the Cu active sites are covered by a layer of electrolyte, forcing the reaction to take place mainly at double phase boundaries. Our work highlights the necessity of controlling GDE substrate microstructure to minimize the parasitic HER and offers a scalable strategy towards high C<sub>≥2</sub> products selectivity.

## Methods

GDE substrates were prepared by electrospinning solutions of 15, 30, and 32 wt% poly(vinylidene-fluoride-co-hexafluoropropylene) (PVDF-HFP) in a 1 wt% solution of tetraethylammonium bromide (TEABr) in dimethylformamide (DMF) at 30 kV. These substrates were used to prepare GDEs by single-sided deposition of a Cu catalyst layer with a nominal thickness of 500 nm employing physical vapor deposition (Cu-GDE). Pore size and water entry pressure measurements on both substrates and GDEs are carried out by capillary flow porometry. Details on the fabrication and structural characterization are provided in the ESI† and in Fig. S1–S4.

Cu-GDE product selectivity and activity during CO<sub>2</sub>RR was assessed in a three-compartment electrochemical cell. Details of the cell assembly are shown in Fig. S5 (ESI†). Briefly, the GDE sits between a gas chamber where the CO<sub>2</sub> reactant flows, and a liquid chamber, which contains the catholyte (1M KCl) and a Ag/AgCl reference electrode. The anolyte (1M KHCO<sub>3</sub>) is separated from the catholyte by a cation exchange membrane (Nafion 117). A Ti grid coated with IrO<sub>x</sub> serves as anode for the oxygen evolution reaction, oversizing the anode to avoid limiting the cathodic performance. Gaseous and liquid reaction products are quantified using gas and liquid chromatography, respectively (details are reported in the ESI†).

## Results and discussion

Fig. 1a–c shows cross-sectional scanning electron microscopy (SEM) images of Cu-GDEs obtained by electrospinning solutions with increasing polymer concentration. The pore size distribution shown in Fig. 1d, from which we extract the mean pore sizes of the GDEs was determined by capillary flow porometry (see Fig. S3 and S4 for more details, ESI†). With increasing polymer concentration in the electrospinning solution, the mean pore size increases from 0.2 to 0.7 to 1.1 μm. To get information on the GDEs' wetting behavior, we also measure their water entry pressure, which is the pressure of water required to penetrate a dry, porous, hydrophobic substrate. The water entry pressure is related to the polymer's hydrophobicity, and thus to its chemistry, but also depends on the substrate pore size. As the GDE substrates are made of the same polymer, their different water entry pressures are mainly dictated by their

**Fig. 1** SEM images of Cu-GDEs with mean pore size of (a) 0.2 μm (15% PDVF-HFP), (b) 0.7 μm (30% PDVF-HFP), and (c) 1.1 μm (32% PDVF-HFP), and (d) corresponding pore size distribution, and (e) water entry pressure vs. mean pore size. Note the different scale bars in the SEM images. The obtained fibers (darker contrast) are coated with Cu (lighter contrast) close to the top surface of the GDE.

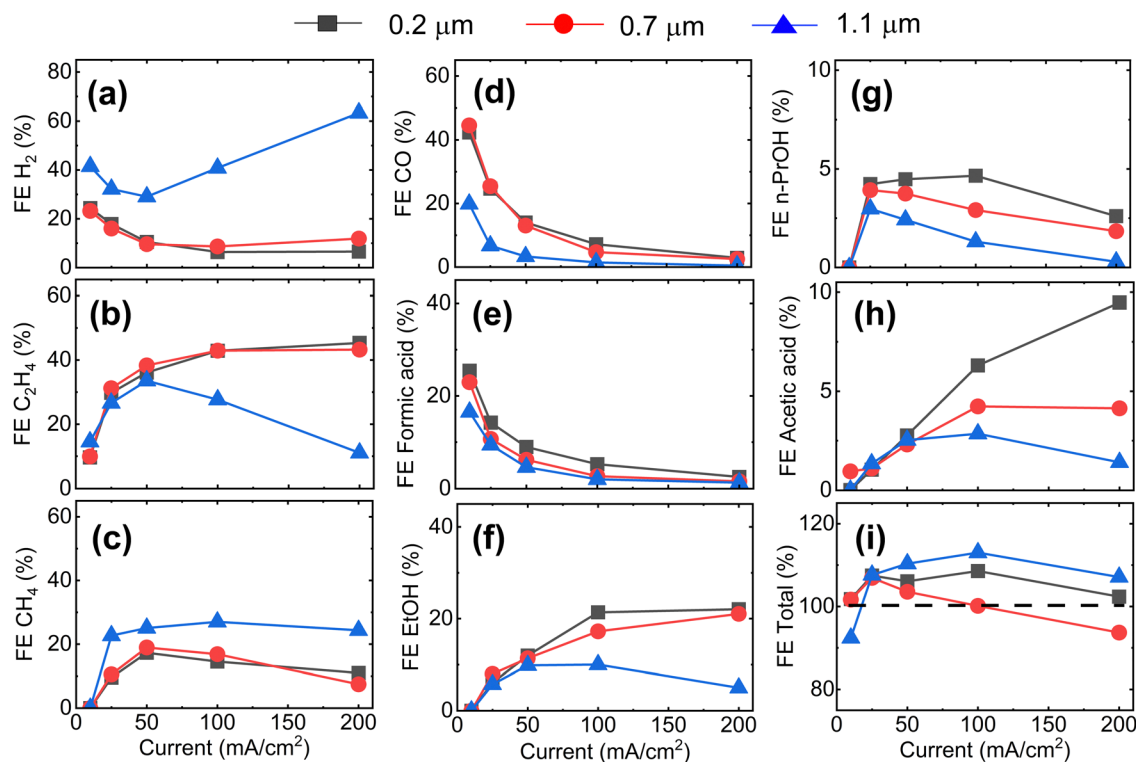

different mean pore size, as described by the Young–Laplace equation. Fig. 1e shows the correlation between these morphological descriptors, with GDEs with smaller mean pore size showing higher water entry pressures.

Next, we analyze the product selectivity and activity of the GDEs during CO<sub>2</sub>RR. Fig. 2 displays the faradaic efficiencies (FEs) towards the main gaseous products (H<sub>2</sub>, C<sub>2</sub>H<sub>4</sub>, CH<sub>4</sub> and CO) and liquid products (formic acid, acetic acid, EtOH, and *n*-PrOH), and the total FE as a function of applied current density for the Cu-GDEs with mean pore sizes 0.2 μm, 0.7 μm, and 1.1 μm. The total FE also accounts for minor gaseous products such as allyl alcohol, propane, propene, propionaldehyde, acetaldehyde, and acetone, each accounting for FE < 1%. Inspection of Fig. 2 reveals that when increasing the current density from 10 to 50 mA cm<sup>-2</sup>, all GDEs show a clear decrease of FE towards H<sub>2</sub>, CO, and formic acid, a strong increase towards C<sub>2</sub>H<sub>4</sub>, ethanol, and acetic acid, as well as a mild increase in FE towards CH<sub>4</sub> irrespective of their mean pore size. In this current density range, the only difference between the GDEs is a lower FE towards CO and formic acid and a higher FE towards H<sub>2</sub> for the GDE with 1.1 μm mean pore size. When increasing the current density further from 50 to 200 mA cm<sup>-2</sup>, the FE of the GDE with 1.1 μm mean pore size shifts distinctly towards H<sub>2</sub>. In comparison, for the GDEs with 0.2 and 0.7 μm mean pore size, the FE for C<sub>2</sub>H<sub>4</sub> continues to increase up to 200 mA cm<sup>-2</sup>, where a remarkable value of

~ 50% is achieved. For *n*-PrOH, an initial increase followed by a decrease at high current densities is observed. In addition, the FE towards CH<sub>4</sub> decreases for the 0.2 μm and 0.7 μm GDEs with increasing current density, while it stays almost constant for the GDE with 1.1 μm mean pore size. The total FE shown in Fig. 2i falls between 90 and 110% considering all GDEs and all current densities applied. These relative variations, however, do not affect the observed trends with GDE pore size, as these are also present after normalization of the total FEs to 100% (Fig. S6, ESI†). The statistical error associated to the FE was assessed by evaluating the performance of nominally identical GDEs with 0.2 μm pore size. This analysis is given in Fig. S10 (ESI†), from which we extract a relative standard deviation of ±5% for the FE of the main gaseous products, averaged over a 1 h measurement at 200 mA cm<sup>-2</sup>. We also provide the current vs. voltage slopes in Fig. S7 (ESI†).

The plateau in FE towards C<sub>≥2</sub> product observed in Fig. 2b is a first evidence for CO<sub>2</sub>RR taking place at double-phase boundaries between the solid Cu catalyst and liquid electrolyte with dissolved CO<sub>2</sub>,<sup>30</sup> rather than at triple phase boundaries (between catalyst, electrolyte, and gaseous CO<sub>2</sub>). As direct gaseous access is unlikely to be restricted in our highly porous GDEs (~80% porosity by liquid pycnometry), these results suggest that the active sites of the Cu catalyst are covered by an electrolyte layer, which indirectly limits the availability of CO<sub>2</sub>. The uniform behaviour of the GDEs below 50 mA cm<sup>-2</sup> is consistent with this hypothesis.

**Fig. 2** Faradaic efficiency of Cu-GDEs with different mean pore size as a function of current density towards (a) H<sub>2</sub> (b) C<sub>2</sub>H<sub>4</sub>, (c) CH<sub>4</sub>, (d) CO, (e) formic acid (f) EtOH (g) *n*-PrOH (h) acetic acid and (i) total FE. Additional trace compounds (FE < 1%) including allyl alcohol, propane, propene, propionaldehyde, acetaldehyde, and acetone were detected in the gas products and are accounted for in the total FE. The FE towards gaseous products is assessed every five minutes and it is averaged over one hour of reaction, while the FE towards liquid products is determined at the end of the reaction.

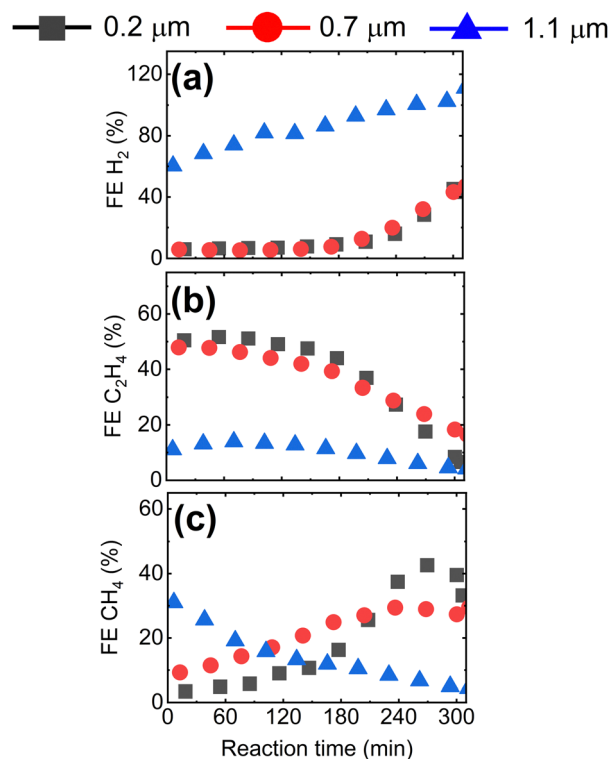

**Fig. 3** Faradaic efficiency for  $\text{H}_2$ ,  $\text{C}_2\text{H}_4$ , and  $\text{CH}_4$  as function of applied current for GDEs with different mean pore size during  $\text{CO}_2\text{RR}$  (a)–(c) and CORR (d)–(f). To avoid resistive heating at current densities  $>200 \text{ mA cm}^{-2}$ , we reduce the exposed area of the catalyst from  $1 \text{ cm}^2$  to  $0.2 \text{ cm}^2$  for  $\text{CO}_2\text{RR}$  by masking the GDEs with a polytetrafluoroethylene tape. The voltage of the reactions is reported in Fig. S8 (ESI<sup>†</sup>). Note the difference in the scale of the x-axis for  $\text{CO}_2\text{RR}$  and for CORR plots.

To gather additional evidence for  $\text{CO}_2\text{RR}$  taking place at double-phase boundaries, we extend the  $\text{CO}_2\text{RR}$  experiment to higher current densities up to  $600 \text{ mA cm}^{-2}$ . In parallel, we assess the GDE performance during the electrochemical reduction of CO (CORR). Fig. 3a–c displays the FE for the main gaseous products ( $\text{H}_2$ ,  $\text{C}_2\text{H}_4$ , and  $\text{CH}_4$ ) during  $\text{CO}_2\text{RR}$  at current densities up to  $600 \text{ mA cm}^{-2}$ . Results are consistent with Fig. 2, even showing a higher maximum FE of  $\sim 55\%$  for  $\text{C}_2\text{H}_4$  at  $200 \text{ mA cm}^{-2}$  for the GDE with the smallest mean pore size of  $0.2 \mu\text{m}$ . Maxima in FE are also observed for  $\text{CH}_4$  shifting from  $400 \text{ mA cm}^{-2}$  to  $200 \text{ mA cm}^{-2}$  with increasing GDE mean pore size followed by a rapid rise in FE for  $\text{H}_2$  at higher current densities. For CORR shown in Fig. 3d–f, we observe that the highest FE towards  $\text{C}_2\text{H}_4$  is achieved at a ten-fold lower current density compared to  $\text{CO}_2\text{RR}$  for the GDE with the mean pore size of  $0.2 \mu\text{m}$ , which is attributed to the lower solubility of CO in water ( $1 \text{ mM}$  at  $25^\circ\text{C}$ ).<sup>31</sup> At higher current densities, the FE for  $\text{C}_2\text{H}_4$  falls rapidly. A similar behavior is observed for the GDEs with  $0.7 \mu\text{m}$  and  $1.1 \mu\text{m}$  mean pore size with the maxima shifted towards lower current densities.

These findings show that a maximum FE towards  $\text{C}_2\text{H}_4$  is obtained at an optimum value of the current density which depends on the GDE's mean pore size. The selectivity towards  $\text{C}_1$  products is promoted when the availability of protons is substantial (indicated by high parasitic HER), while the selectivity towards  $\text{C}_{\geq 2}$  products is maximized when proton

**Fig. 4** Faradaic efficiency for (a)  $\text{H}_2$ , (b)  $\text{C}_2\text{H}_4$ , and (c)  $\text{CH}_4$  at  $200 \text{ mA cm}^{-2}$  as a function of time for GDEs with mean pore size  $0.2 \mu\text{m}$ ,  $0.7 \mu\text{m}$ , and  $1.1 \mu\text{m}$ .

availability is limited (low HER). In addition, the CORR results provide a strong evidence for the double phase boundary hypothesis, as the much more severe mass transport limitations observed there are consistent with the 35-fold lower solubility of CO in water compared with  $\text{CO}_2$ . As the thickness of the electrolyte layer covering the catalyst is the key parameter governing CO/ $\text{CO}_2$  availability, the results reveal a correlation between GDE pore size and electrolyte layer thickness, with smaller pores yielding thinner electrolyte layers.

Having shown that the GDE microstructure dictates  $\text{CO}_2\text{RR}$  product selectivity, we now study the impact of GDE microstructure on  $\text{CO}_2\text{RR}$  stability. In Fig. 4, we present the evolution of the  $\text{CO}_2\text{RR}$  FEs during 300 min operation of the Cu-GDEs at  $200 \text{ mA cm}^{-2}$  (see Fig. S9 for other products, ESI<sup>†</sup>). During the first 180 min, the FE toward  $\text{H}_2$  remains below 5% for the GDEs with mean pore size of  $0.2 \mu\text{m}$  and  $0.7 \mu\text{m}$ , then progressively increases to 40% after 300 min. For the GDE with the largest mean pore size of  $1.1 \mu\text{m}$ , the FE for  $\text{H}_2$  starts at 60% and increases to 100% after 300 min. The FE for  $\text{C}_2\text{H}_4$  follows an opposite trend and starts at 50% for the GDEs with  $0.2 \mu\text{m}$  and  $0.7 \mu\text{m}$  mean pore size, but then gradually decays over time. A more complicated evolution is observed for the FE for  $\text{CH}_4$ : for the GDEs with  $0.2 \mu\text{m}$  and  $0.7 \mu\text{m}$  mean pore size, it slowly increases and reaches a maximum after several hours, while for the GDE with  $1.1 \mu\text{m}$  mean pore size, the FE for  $\text{CH}_4$  reaches a maximum very early and then decreases continuously.

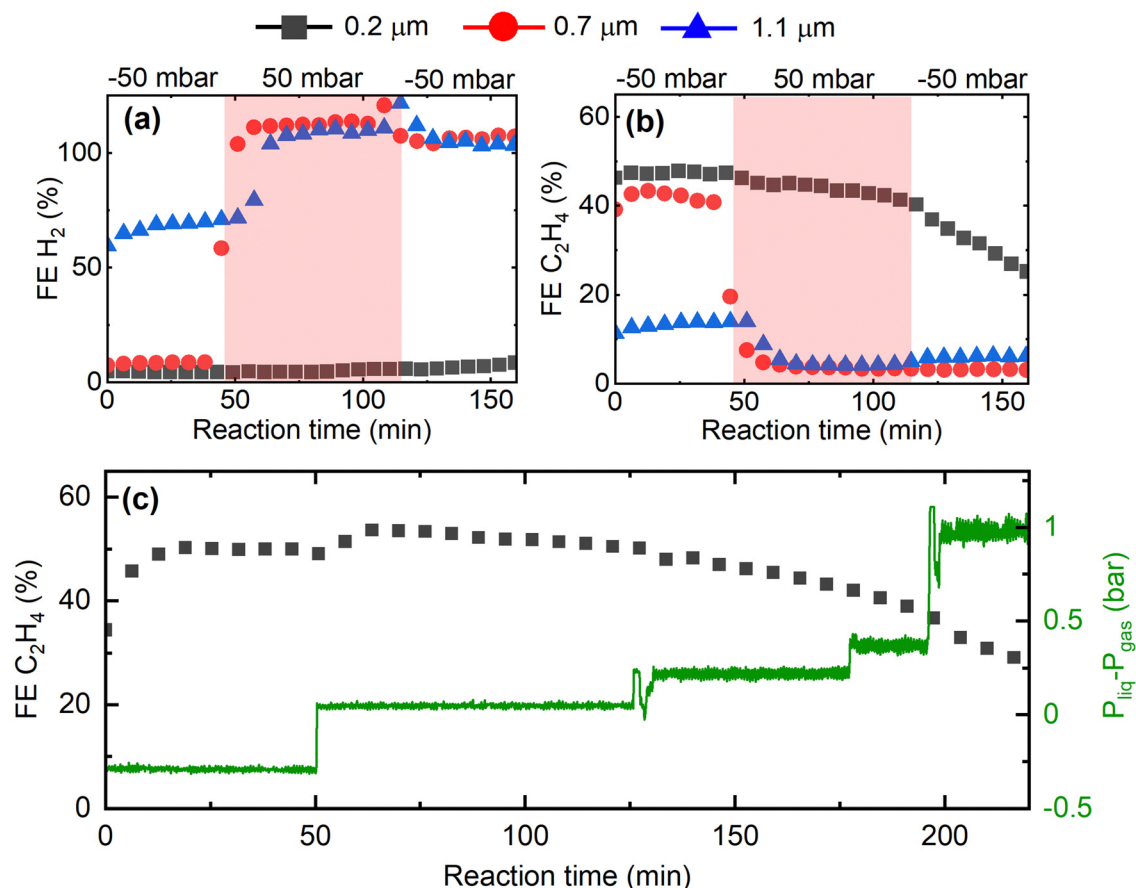

Overall, we observe a gradual shift from  $\text{C}_2\text{H}_4$  to  $\text{CH}_4$  to  $\text{H}_2$  during long-term  $\text{CO}_2\text{RR}$ , which we ascribe to precipitation of

carbonates in the GDE resulting in flooding of the Cu catalyst by the electrolyte, as described previously.<sup>32–34</sup> According to the reported mechanism, high local pH values in the electrolyte near the Cu catalyst, resulting from localized proton depletion, lead to the precipitation of carbonates or bicarbonates, which are highly hygroscopic. Over time, the accumulation of these salts in the GDE causes a loss of hydrophobicity, and promotes electrolyte penetration into the GDE. As a result, catalyst flooding worsens CO<sub>2</sub> mass transport and favors parasitic HER by increasing the diffusion pathway length of CO<sub>2</sub>. As we are employing strongly hydrophobic GDE substrates, we have never observed complete, macroscopic flooding of the GDE. However, it is still likely that local precipitation of salts close to the Cu catalyst takes place, reducing local hydrophobicity and causing an increase in the thickness of the electrolyte layer covering the catalyst. One strategy to mitigate or reduce the decay of performance over time is to periodically refresh the electrolyte and/or to periodically interrupt the reaction.<sup>35</sup> As we focus here on the effect of the morphology of the GDE on their performance, we refrain from using these strategies in this study.

An additional parameter for controlling local wetting of the GDE is provided by the pressure difference between the liquid

electrolyte and the reactant gas inside the electrochemical cell. A negative pressure difference ( $\Delta P < 0$ ), *i.e.* a gas overpressure, can hinder electrolyte penetration into the GDE and consequently prevent catalyst flooding, while a positive pressure difference ( $\Delta P > 0$ ), *i.e.* an electrolyte overpressure, can promote it. Fig. 5 displays the results of a CO<sub>2</sub>RR experiment in which we purposefully vary the pressure difference by using needle valves, monitoring the change with pressure sensors. As can be seen in Fig. 5a and b, switching the pressure difference from negative to slightly positive (only 50 mbar) immediately causes the C<sub>2</sub>H<sub>4</sub> selectivity to drop to zero while H<sub>2</sub> selectivity dominates the product distribution for the GDEs with 0.7  $\mu\text{m}$  and 1.1  $\mu\text{m}$  mean pore size. Only the GDE with 0.2  $\mu\text{m}$  mean pore size is capable of maintaining high C<sub>2</sub>H<sub>4</sub> selectivity despite the pressure change, highlighting again the importance of small mean pore sizes. Note that 50 mbar liquid overpressure is insufficient to push the liquid electrolyte through the GDE, as even the water entry pressure for the GDE with the largest pore size is 0.6 bar. Further, this loss of selectivity is irreversible even if the pressure difference is set back to negative values. Notably, the GDE with smallest mean pore size of 0.2  $\mu\text{m}$  is unaffected by the change in pressure

**Fig. 5** Faradaic efficiency for (a) H<sub>2</sub> and (b) C<sub>2</sub>H<sub>4</sub> at 200 mA cm<sup>-2</sup> as a function of time and pressure for GDEs with mean pore size 0.2  $\mu\text{m}$ , 0.7  $\mu\text{m}$ , and 1.1  $\mu\text{m}$ . In the first 60 minutes, the pressure difference between liquid and gas chamber is negative ( $\Delta P < 0$ ), then switched to positive ( $\Delta P = 50$  mbar, liquid overpressure) for 60 minutes, finally the pressure is reverted back to negative values ( $\Delta P < 0$ ). (c) Faradaic efficiency towards C<sub>2</sub>H<sub>4</sub> at 200 mA cm<sup>-2</sup> as a function of time and with stepwise increase of pressure from  $\Delta P \sim -200$  mbar to  $\Delta P \sim 1000$  mbar for the GDE with mean pore size 0.2  $\mu\text{m}$ .

difference even up to  $\Delta P > 1000$  mbar, as shown in Fig. 5c. From an engineering point of view, GDEs with small pores thus offer the attractive advantage of withstanding pressure spikes both in gas and in liquid overpressure, which could take place, for example during CO<sub>2</sub>RR startup.

Our findings provide multiple evidence that, for all mean pore sizes considered, the active sites of the Cu GDE are covered by an electrolyte layer, and that the thickness of this layer is governed by GDE pore size, with smaller pores yielding thinner electrolyte layers. This means that, in these polymer-based GDEs, double-phase boundaries dominate the CO<sub>2</sub>RR or CORR reactivity over triple phase boundaries. We also note that, while thinner electrolyte layers cause enhanced CO<sub>2</sub> transport, they also yield a more limited transport of H<sup>+</sup>/OH<sup>-</sup> to/from the catalyst active sites. The H<sup>+</sup>/OH<sup>-</sup> transport limitation will make the pH shift more strongly to higher values during CO<sub>2</sub>RR for small pore size GDEs, potentially also influencing the product selectivity.

Considering 200 mA cm<sup>-2</sup> as a technologically relevant threshold value for the current density, our results show that the upper limit for the GDE's mean pore size is certainly below 1.1 μm, likely below 0.7 μm. In addition, we can expect a lower limit dictated by the pore size at which the mass transport of CO<sub>2</sub> to the catalyst transitions from pressure driven to Knudsen diffusion, *i.e.* when the mean free path of the gas molecule is comparable with the diameter of the pore, which is ~0.05 μm for CO<sub>2</sub> gas at room pressure.<sup>36</sup> These mass transport considerations, in agreement with our experimental results, indicate an optimal pore size for GDE substrates between ~0.05 and ~0.7 μm to maximize C<sub>2</sub>H<sub>4</sub> selectivity on Cu catalysts.

Nonetheless, we note that C<sub>2</sub>H<sub>4</sub> is always synthesized alongside a variety of other C<sub>≥2</sub> products, highlighting the need for strategies able to steer the selectivity toward a single C<sub>≥2</sub> product. Several different approaches in this direction have been recently assessed, from the development of engineered pathways for CO<sub>2</sub> and H<sup>+</sup>/OH<sup>-</sup> transport,<sup>37</sup> to the insertion of hydrophobic zones near the active sites,<sup>23</sup> to the use of complex electrolyte solutions.<sup>30,38</sup> As these approaches have yielded important – but not sufficient – selectivity improvements, we expect that a higher degree of control of the local catalyst environment, for example achieved by the targeted introduction of hydrophobic – hydrophilic zones within the GDE, may be necessary to obtain a single C<sub>≥2</sub> product during CO<sub>2</sub>RR.

## Conclusions

In conclusion, we employed electrospinning and physical vapor deposition to prepare Cu GDEs with tunable substrate pore sizes and water entry pressures. We demonstrated that GDE mean pore size dictates product selectivity and were able to achieve a remarkable FE of ~50% towards C<sub>2</sub>H<sub>4</sub> and ~75% towards C<sub>≥2</sub> products with the GDE with smallest mean pore size of 0.2 μm. Based on mass transport considerations, we estimate the optimal pore size of the substrate to be between ~0.05 and ~0.7 μm to maximize C<sub>≥2</sub> product selectivity.

Finally, we assessed the capability of GDEs to sustain liquid electrolyte overpressures and found that GDEs with the smallest mean pore size are able to withstand up to 1 bar overpressure, while GDEs with larger mean pore size (above 0.7 μm) suddenly and irreversibly lose their selectivity towards carbon products in favor of HER with just 50 mbar of electrolyte overpressure. The dependence of the highest FE towards C<sub>2</sub>H<sub>4</sub> on the pore size for both CO<sub>2</sub>RR and CORR, the progressive increase of FE towards H<sub>2</sub> over time and the increased sensitivity of GDEs with large pore size to liquid overpressure provide evidence for the presence of an electrolyte layer covering the active site of the Cu catalyst, and thus of the dominance of double phase boundary reactivity. To complement the picture emerging from electrochemical measurements with direct experimental information on the local catalyst environment, future studies will focus on *in situ* methods.
