## Metal–organic frameworks as O<sub>2</sub>-selective adsorbents for air separations†

David E. Jaramillo,<sup>a</sup> Adam Jaffe,<sup>‡a</sup> Benjamin E. R. Snyder,<sup>a</sup> Alex Smith,<sup>b</sup> Eric Taw,<sup>cd</sup> Rachel C. Rohde,<sup>b</sup> Matthew N. Dods,<sup>a</sup> William DeSnoo,<sup>§b</sup> Katie R. Meihaus,<sup>a</sup> T. David Harris,<sup>b</sup> Jeffrey B. Neaton<sup>bef</sup> and Jeffrey R. Long<sup>id\*acd</sup>

Oxygen is a critical gas in numerous industries and is produced globally on a gigatonne scale, primarily through energy-intensive cryogenic distillation of air. The realization of large-scale adsorption-based air separations could enable a significant reduction in associated worldwide energy consumption and would constitute an important component of broader efforts to combat climate change. Certain small-scale air separations are carried out using N<sub>2</sub>-selective adsorbents, although the low capacities, poor selectivities, and high regeneration energies associated with these materials limit the extent of their usage. In contrast, the realization of O<sub>2</sub>-selective adsorbents may facilitate more widespread adoption of adsorptive air separations, which could enable the decentralization of O<sub>2</sub> production and utilization and advance new uses for O<sub>2</sub>. Here, we present a detailed evaluation of the potential of metal–organic frameworks (MOFs) to serve as O<sub>2</sub>-selective adsorbents for air separations. Drawing insights from biological and molecular systems that selectively bind O<sub>2</sub>, we survey the field of O<sub>2</sub>-selective MOFs, highlighting progress and identifying promising areas for future exploration. As a guide for further research, the importance of moving beyond the traditional evaluation of O<sub>2</sub> adsorption enthalpy,  $\Delta H$ , is

David Jaramillo completed his PhD at UC Berkeley with Professor Jeffrey Long as an NSF Graduate Research Fellow. In the Long group, David worked on developing new metal–organic frameworks that engage in strong orbital interactions for gas storage and gas separations. Before graduate school, David studied Chemistry and Philosophy at Harvard. He is currently

Co-Founder and CTO of Verne, a Bay Area startup developing hydrogen solutions for the heavy-duty transportation sector.

Adam Jaffe is an Assistant Professor of Chemistry at the University of Notre Dame. He received his A.B. in Chemistry from Princeton University (2012) and his PhD in Inorganic Chemistry working with Prof. Hemamala I. Karunadasa at Stanford University (2017). He joined the lab of Prof. Jeffrey R. Long at the University of California, Berkeley (2017–2021) as an NIH postdoctoral fellow

evaluating the separation of O<sub>2</sub> from air in redox-active porous materials. He arrived at Notre Dame in 2021 where the Jaffe group now develops hybrid material platforms and studies their structure-property relationships, including at high pressure.

emphasized, and the free energy of O<sub>2</sub> adsorption,  $\Delta G$ , is discussed as the key metric for understanding and predicting MOF performance under practical conditions. Based on a proof-of-concept assessment of O<sub>2</sub> binding carried out for eight different MOFs using experimentally derived capacities and thermodynamic parameters, we identify two existing materials and one proposed framework with nearly optimal  $\Delta G$  values for operation under user-defined conditions. While enhancements are still needed in other material properties, the insights from the assessments herein serve as a guide for future materials design and evaluation. Computational approaches based on density functional theory with periodic boundary conditions are also discussed as complementary to experimental efforts, and new predictions enable identification of additional promising MOF systems for investigation.

## 1. Introduction

### 1.1 Current air separation technologies and their limitations

Oxygen is one of the foundational gases of the industrial sector.<sup>1</sup> Today, fossil fuel combustion alone consumes O<sub>2</sub> directly from air on a massive scale of ~25 gigatonnes per year, about 8 gigatonnes more than the annual natural production of O<sub>2</sub>.<sup>2</sup>

Moreover, enriched (>21%) or high-purity oxygen (>95%) is essential for numerous applications, including within the medical and aerospace industries,<sup>1,3</sup> as well as in a variety of chemical processes, such as the production of phthalic anhydride, acetaldehyde synthesis *via* the Wacker Process, and ethylene oxide production.<sup>1,4</sup> The COVID-19 pandemic has also highlighted the importance of medical-grade oxygen and its existing supply chain issues.<sup>5</sup> These and many other processes

*Dr Benjamin Snyder is currently an Arnold O. Beckman Postdoctoral Fellow working with Professor Jeffrey Long at UC Berkeley to design metal-organic frameworks as solid adsorbents for gas separations. Previously, he was an NSF Graduate Research Fellow and Stanford Graduate Fellow with Professor Edward Solomon at Stanford University, where he developed new site-selective*

*spectroscopic probes of transition metal active sites in heterogeneous catalysts. Dr Snyder is broadly interested in the Physical Inorganic Chemistry of porous materials.*

*Jeffrey B. Neaton is a Professor in the Department of Physics at the University of California, Berkeley, a Senior Faculty Scientist in the Materials Sciences Division at Lawrence Berkeley National Laboratory, and a Member of the Kavli Energy NanoSciences Institute at Berkeley. He has been the Associate Laboratory Director for Energy Sciences at Berkeley Lab since 2017. He received his*

*PhD in physics from Cornell University in 2000, and was a postdoc at Rutgers University until 2003. Neaton was awarded the Presidential Early Career Award for Scientists and Engineers, and he is a fellow of the American Physical Society.*

*Alex Smith received his B.A. in 2018 from the University of Chicago, where he studied Physics and Computer Science while researching ligated gold nanoparticles with molecular dynamics. In his PhD work with Professor Jeffrey B. Neaton he studies small molecule binding in metal-organic frameworks with density functional theory.*

*Jeffrey R. Long is the C. Judson King Distinguished Professor of Chemistry and Chemical & Biomolecular Engineering at the University of California, Berkeley and a Faculty Senior Scientist in the Materials Sciences Division at Lawrence Berkeley National Laboratory. His research involves the synthesis and physical characterization of new materials with potential applications in sustainable*

*energy and environmental remediation, and his 375 publications have received more than 85 000 citations. He co-founded and directed the start-up company Mosaic Materials, which was recently acquired by Baker Hughes and is developing metal-organic frameworks for low-energy carbon dioxide capture.*

depend on the separation of oxygen from air. As a result, this process is performed on a scale of hundreds of millions of tonnes per year.<sup>6</sup>

Importantly, high-purity O<sub>2</sub> is also critical for next-generation carbon capture processes poised to play a critical role in reducing emissions from large-scale combustion plants. For example, oxy-fuel power plants, which are currently in the pilot stage, use O<sub>2</sub> (~95%) instead of air to produce a concentrated CO<sub>2</sub> flue gas stream.<sup>7–9</sup> This process renders post-combustion CO<sub>2</sub> capture more viable by reducing the energy needed for regeneration while also decreasing NO<sub>x</sub> emissions. Likewise, high-purity O<sub>2</sub> is necessary for carrying out pre-combustion CO<sub>2</sub> capture in fossil fuel gasification plants.<sup>10,11</sup>

Approximately 70% of O<sub>2</sub> generated in industry is obtained *via* cryogenic distillation of air,<sup>12</sup> which is predominantly a centralized process that takes place in large air separation plants. First pioneered by Linde in the late 19<sup>th</sup> century, this process exploits the small difference in the boiling points of O<sub>2</sub> and N<sub>2</sub> (Table 1).<sup>1,13</sup> In brief, low-temperature air is fed into large distillation columns that feature pressure and temperature gradients and numerous trays where liquid and vapor phases equilibrate. Within these columns, nitrogen vapor rises and increases in purity, while liquid oxygen descends the columns and increases in purity. Cryogenic distillation plants can generate O<sub>2</sub> with 95% purity or higher at 1000 to 5000 tonnes per day. This method is a remarkable feat of engineering, considering the small difference in vapor pressure between the two gases. Nevertheless, cryogenic separation units are very capital-intensive projects that require operation at relatively high capacities.<sup>14</sup> As a result, the energy required to separate one tonne of O<sub>2</sub> from air is approximately 245 kW h (Table 2),<sup>6,14</sup> more than four times greater than the minimum separation work of 58 kW h per tonne at 25 °C (see ESI Section S1†).<sup>14</sup> Further, owing primarily to the similar vapor pressures of argon and O<sub>2</sub>,<sup>13</sup> achieving O<sub>2</sub> purities greater than 95% requires additional expensive refrigeration that increases the overall energy demand per tonne of O<sub>2</sub>.<sup>6</sup>

Adsorptive air separation represents the second most common process for oxygen production, accounting for ~20% of O<sub>2</sub> produced in industry.<sup>14</sup> This approach currently exploits differences in the polarizability and quadrupole moment of O<sub>2</sub> and N<sub>2</sub> (Table 1). Briefly, pressurized air is fed through beds containing an adsorbent that selectively binds N<sub>2</sub>. The most commonly used adsorbent is a low-silica zeolite exchanged with lithium ions, known as Li-LSX,<sup>12,15</sup> which features exposed Li<sup>+</sup> sites that preferentially interact with N<sub>2</sub>. Once the adsorbent is saturated with the gas, the bed is depressurized to near ambient pressure,

resulting in elution of an O<sub>2</sub>-enriched stream, followed by N<sub>2</sub>. A process operating under such conditions is referred to as pressure swing adsorption (PSA). Air can also be fed into the adsorbent bed at near ambient pressure, and in this case vacuum or heat can then be applied to regenerate the adsorbent, in so-called vacuum swing adsorption (VSA) or temperature swing adsorption (TSA) processes.<sup>12,14,16,17</sup> Further, the above separation methods can be combined to engender pressure-temperature or vacuum-temperature swing adsorption processes. Importantly, adsorptive air separations can serve a complementary role to cryogenic distillation, as they can operate under a more variable load (for instance, by changing the number of adsorbent beds in use), are substantially less capital-intensive for small-scale applications, and entail minimal startup time. Adsorptive air separation plants typically consume 500 kW h per tonne of O<sub>2</sub> produced at 90–95% purity,<sup>14,18</sup> although a much lower value of 270 kW h per tonne of O<sub>2</sub> has been reported (Table 2).<sup>12</sup> This energy demand is nearly double that of cryogenic distillation, and the resulting oxygen purity is generally lower. This higher energy cost arises due to the need to regenerate the adsorbent, as discussed above. Additionally, zeolites typically exhibit low N<sub>2</sub> uptake, and therefore substantial quantities of adsorbent material are required—roughly 1 tonne of zeolite is needed for producing 1 tonne of O<sub>2</sub> per day. In all, these shortcomings preclude the more wide-spread application of Li-LSX adsorbents for air separations.

Polymeric membrane-based air separations are the youngest commercial technology for extracting O<sub>2</sub> from air, and operate by passing an air stream through a series of membrane units.<sup>18–20</sup> These processes function under a solution-diffusion mechanism and discriminate oxygen and nitrogen based on their permeabilities. Industrially relevant membranes are permselective with respect to oxygen, and so the resulting permeate is O<sub>2</sub>-enriched air. As a result of their mechanism of operation, membrane separations can be carried out continuously under ambient conditions, without the need for regeneration. As such, polymer membranes have the potential to offer considerable reductions in capital costs and operating expenses relative to adsorption and cryogenic distillation. However, for the majority of membranes studied to date, permeate O<sub>2</sub> concentrations are limited by the minor solubilization difference between O<sub>2</sub> and N<sub>2</sub>.<sup>21</sup> This shortcoming, combined with similarities in the kinetic diameters of N<sub>2</sub> and O<sub>2</sub>, manifests as a permeability-selectivity tradeoff that limits permeate purities to below 40–50% O<sub>2</sub>.<sup>18,21</sup> Note that ceramic membranes, which function through a different mechanism, may find use in industrial applications. However, these membranes typically require very high temperatures to operate, in the range of 800–900 °C.<sup>19,22</sup>

Table 1 Relevant properties of the key components of air

	N <sub>2</sub>	O <sub>2</sub>	Ar
Molar fraction	0.78	0.21	00.93
Normal boiling point (K)	77.3	90.2	87.3
Kinetic diameter (Å)	3.64	3.47	3.54
Polarizability × 10 <sup>25</sup> (cm <sup>3</sup> )	17.703	15.812	16.411
Quadrupole moment × 10 <sup>26</sup> (esu cm <sup>2</sup> )	1.52	0.39	0
Electron affinity (eV)	<0	0.450	<0

## 1.2 The potential impact of O<sub>2</sub>-selective adsorbents in air separations

In general, established air separation technologies operate by distinguishing O<sub>2</sub> and N<sub>2</sub> based on relatively small differences in their boiling points, polarizabilities, and quadrupole moments. However, the property that most distinguishes O<sub>2</sub> from N<sub>2</sub> (and Ar) is its electron affinity (Table 1). Oxygen can readily accept one or two electrons from a single metal center, whereas nitrogen is generally redox-inactive.<sup>23</sup> Biological

Table 2 Overview of current air separation processes

	Cryogenic distillation <sup>a</sup>	Adsorptive separations <sup>b</sup>	Membrane separations <sup>c</sup>
Operating pressures	1–6 bar	0.2–6 bar	1–6 bar
Operating temperatures	77–298 K	298–318 K	298–318 K
O <sub>2</sub> purity achieved	>95%	<95%	<50%
O <sub>2</sub> production scale per day	1000 tonnes	100 tonnes	10 tonnes
Largest reported capacity per day	5000 tonnes (Air Liquide)	340 tonnes (Linde)	25 tonnes
Energy demand per tonne	220–270 kW h at 95% purity	500 kW h at 95% purity	300 kW h at 40% purity

<sup>a</sup> Values obtained from ref. 6, 14, and 19. <sup>b</sup> Values obtained from ref. 6, 14, and 19. <sup>c</sup> Values obtained from ref. 6 and 20. The largest reported capacity per day is an estimate from ref. 6.

systems exploit this difference to selectively and reversibly bind O<sub>2</sub> using iron(II)- and copper(I)-containing proteins. In particular, hemoglobin and myoglobin,<sup>24,25</sup> hemerythrin,<sup>26</sup> and hemocyanin<sup>27</sup> are representative examples of proteins containing metal sites that bind O<sub>2</sub> *via* electron transfer.

The realization of adsorbents that are capable of similar strong yet reversible chemisorption of O<sub>2</sub> could transform the air separation industry. Indeed, because the partial pressure of O<sub>2</sub> in air is approximately four times less than that of N<sub>2</sub>, the amount of O<sub>2</sub>-selective adsorbent needed to process a given quantity of air will be one quarter of the quantity needed for an analogous N<sub>2</sub>-selective adsorbent. As a result, even in a scenario where the enthalpy of O<sub>2</sub> binding in an O<sub>2</sub>-selective adsorbent is comparable to the N<sub>2</sub> binding enthalpy in Li-LSX, the overall regeneration energy needed for the O<sub>2</sub>-selective material would be substantially lower, perhaps even 50% lower, assuming the material exhibits a high selectivity for O<sub>2</sub> (ESI Section S2†).<sup>28</sup> In principle, energy-efficient O<sub>2</sub>-selective adsorbents could be implemented in all air separation applications that currently utilize N<sub>2</sub>-selective adsorbents. Additionally, O<sub>2</sub>-selective adsorbents could promote the adoption of new separation processes based on adsorption, including small-scale, variable-load oxygen production, mixed-matrix membrane air separations, and hybrid processes with cryogenic distillation. Overall, a commercially viable O<sub>2</sub>-selective adsorbent could support the decentralization of oxygen production and utilization. Furthermore, O<sub>2</sub>-selective adsorbents with high volumetric capacities might be less costly than cryogenic distillation for mid- and even large-scale air separations, enabling the use of smaller contactors and thereby incurring lower capital expenses.<sup>29</sup>

### 1.3 Metal-organic frameworks as O<sub>2</sub>-selective adsorbents

Research focused on the development of O<sub>2</sub>-selective adsorbents has been ongoing since the 1970s,<sup>30–34</sup> although few materials have been discovered that show thermodynamic selectivity for oxygen over nitrogen, and no O<sub>2</sub>-selective adsorbent is commercially viable at present. Extensive early work focused on the development of molecular compounds that bind O<sub>2</sub> in solution and in the solid-state, most notably featuring cobalt(II).<sup>30–34</sup> However, many of these complexes exhibit poor stabilities, low capacities, and/or irreversible O<sub>2</sub> binding, making them unsuitable for implementation in practical air separation processes. Immobilization of cobalt complexes on porous solid substrates, such as silicates and polymers,<sup>35–37</sup> has been shown to improve

cycling performance, but these materials typically exhibit low O<sub>2</sub> capacities. Considering these shortcomings, an ideal adsorbent would incorporate a high density of redox-active open metal sites immobilized in a robust, rigid porous framework.

Metal-organic frameworks (MOFs) can satisfy both criteria. These crystalline, porous materials are assembled from metal nodes and multitopic organic linkers, and they have emerged as promising candidates to replace traditional adsorbents in numerous industrial applications.<sup>38,39</sup> Structure types of MOFs span a vast library, and in some cases, the as-synthesized material features metal ions with coordination spheres that are completed with solvent molecules introduced during synthesis. Removal of this solvent with heating under reduced pressure (desolvation) generates coordinatively-unsaturated (or “open”) metal centers that can directly interact with adsorbate molecules. The appropriate choice of metal and linker can give rise to a material featuring open metal sites that preferentially bind certain guests based on specific selectivity handles, including gas polarizability,<sup>40</sup>  $\pi$ -acidity,<sup>41</sup> and electron affinity.<sup>42</sup>

In 2010, the metal-organic framework Cr<sub>3</sub>(btc)<sub>2</sub> (btc<sup>3-</sup> = 1,3,5-benzenetricarboxylate) was reported to strongly bind O<sub>2</sub> *via* electron transfer to form a Cr<sup>III</sup>-O<sub>2</sub><sup>-</sup> adduct.<sup>42</sup> The pristine material features a high-density of exposed chromium(II) sites and accordingly displays a high O<sub>2</sub> uptake of 11 wt% at 298 K and an O<sub>2</sub>/N<sub>2</sub> selectivity of ~22 based on single-component adsorption data, notably five times higher than that achieved with cobalt(II) molecules immobilized on silica.<sup>36</sup> This discovery represented a significant advance in the design of O<sub>2</sub>-selective adsorbents and validated the strategy of using redox-active open metal sites in MOFs to target guests based on differences in electron affinity. However, because of the highly exothermic O<sub>2</sub> binding in Cr<sub>3</sub>(btc)<sub>2</sub>, the material capacity decreases with repeated cycling, likely owing to incomplete regeneration of the open metal sites and/or sample degradation. This result therefore also underscores the importance of designing a material exhibiting selective and reversible O<sub>2</sub> binding. Since this seminal work, several studies have focused on the design of MOFs featuring open metal sites that are capable of selective oxygen capture *via* electron transfer chemistry.<sup>43–45</sup> This effort has focused on the chemical space containing monovalent, divalent, and trivalent redox-active metal sites in diverse coordination environments, ranging from anionic oxygen donors in a square pyramidal geometry to nitrogen heterocycles in a trigonal pyramidal geometry.<sup>42–48</sup> Although no MOF has been discovered to date that can be considered a commercially viable

O<sub>2</sub>-selective adsorbent, a number of promising systems and materials design strategies have emerged in recent years.

In this Perspective, we provide a comprehensive survey of the field of O<sub>2</sub>-selective MOFs with the goal of motivating continued progress and new directions in this emerging area of research. A summary of key molecular and biological systems that reversibly bind O<sub>2</sub> is presented in Section 2 to introduce the various species known to form upon binding and reduction of O<sub>2</sub> at open metal sites, as well as relevant design considerations for tuning O<sub>2</sub> binding in MOFs. In Section 3, these concepts are applied in a survey of key framework materials studied to date, which highlights progress and promising areas for future exploration. A critical contribution in the latter section is an in-depth examination of the relevant thermodynamic parameters and working conditions for adsorptive air separation processes. Traditionally, only O<sub>2</sub> binding enthalpies have been presented in the literature along with O<sub>2</sub>/N<sub>2</sub> selectivities at a range of temperatures, precluding meaningful comparisons across materials. We discuss the free energy of O<sub>2</sub> binding as the most important metric to consider when evaluating and designing new MOFs for practical air separations and calculate  $\Delta G$  values for preliminary comparison and benchmarking of existing materials. In Section 4, density functional theory (DFT) approaches for materials evaluation are discussed that can support experimental efforts, and promising MOF targets based on the aforementioned thermodynamic considerations are identified. A brief summary and conclusions are presented in Section 5.

## 2. Design inspiration from molecular and biological examples of reversible O<sub>2</sub> binding

### 2.1 Fundamental considerations

Oxygen binding at a redox-active metal center is an exothermic reaction, facilitated by a strong charge-transfer component. The

resulting enthalpic driving force is offset to varying degrees by an entropic penalty.<sup>49,50</sup> The entropy of O<sub>2</sub> binding is made up of translational, rotational, vibrational, and electronic components (ESI Section S3†), and ultimately cannot exceed the entropy of free O<sub>2</sub>.<sup>51</sup> Typically, the greater the degree of charge transfer, the stronger the metal–oxygen bonding, and the fewer degrees of freedom for the bound O<sub>2</sub>. As such, enthalpy and entropy tend to correlate broadly.<sup>49</sup> Nevertheless, as discussed below, it is important to quantify  $\Delta S$  in addition to  $\Delta H$ , because small entropic changes can meaningfully impact  $\Delta G$  under practical conditions for O<sub>2</sub> separations.

The properties of O<sub>2</sub> as a ligand are determined by its frontier molecular orbitals (Fig. 1a).<sup>49,52</sup> As a result of its filled and stable  $\pi$  and  $\sigma$  bonding orbitals, oxygen features a strong O=O double bond and is a poor  $\pi$  donor. Each  $\pi^*$  orbital contains an unpaired electron, giving rise to the  $S = 1$  ground state of dioxygen. Finally, O<sub>2</sub> features a high-energy vacant  $\sigma^*(2p_z)$  orbital. One- or two-electron reduction results in partial or complete filling of the  $\pi^*$  orbitals and the formation of superoxide (O<sub>2</sub><sup>•−</sup>) or peroxide (O<sub>2</sub><sup>2−</sup>) ligands, respectively. Successive reductions weaken and break the O–O  $\pi$  bond, simultaneously stabilizing the  $\sigma^*(2p_z)$  orbital such that it can participate in back-bonding interactions.<sup>53</sup> While it is generally useful to classify oxygen as a ligand according to the level of reduction, from neutral dioxygen to peroxide, transition metal–O<sub>2</sub> complexes can be highly covalent, which can complicate the assignment of formal oxidation states.

### 2.2 Dioxygen complexes

Stable metal–O<sub>2</sub> molecular complexes are rare because neutral O<sub>2</sub> is generally a poor ligand. Nonetheless, there are cases where O<sub>2</sub> binding induces a perturbation of the metal electronic structure that imparts stability in the absence of appreciable net electron transfer. For example, the Pauling and Coryell model of hemoglobin involves O<sub>2</sub> binding to an initially high-spin ( $S = 2$ )

Fig. 1 (a) Qualitative molecular orbital diagram of dioxygen. (b) Qualitative electronic structure of an  $S = 1$  end-on  $\text{Cu}^{\text{II}} - \text{O}_2^{\bullet-}$  complex, with key orbital interactions highlighted. (c) Qualitative electronic structure of a side-on  $\text{Ti}^{\text{IV}} - \text{O}_2^{2-}$  complex, showing two molecular orbital interactions. For the resulting molecular orbitals, the bond type is indicated by the nature of the M–O<sub>2</sub> interaction, and the contributing O–O bond type is indicated in parentheses.

heme iron(II) center, resulting in singlet O<sub>2</sub> bound to a low-spin (*S* = 0) iron(II).<sup>54</sup> This model is qualitatively correct for the picket fence iron porphyrin, Fe<sup>II</sup>(TpivPP)(1-MeIm) (TpivPP = meso-tetra(α,α,α,α-o-pivalamidophenyl)porphyrin; 1-MeIm = 1-methylimidazole),<sup>51,55,56</sup> a hemoglobin model complex, but is not fully descriptive of hemoglobin (see Section 2.6).<sup>57</sup> While there is no discrete electron transfer from iron to O<sub>2</sub> in this complex, the binding is nonetheless very exothermic in the solid state ( $\Delta H = -65.3 \text{ kJ mol}^{-1}$ , Table 3), and importantly reversible.<sup>51</sup> Indeed, no degradation of the complex was observed over the course of more than 200 O<sub>2</sub> binding/vacuum cycles. This strong yet reversible binding stems in part from strong backbonding from the metal into the O<sub>2</sub> π\* orbital, enabled by the high degree of porphyrin-iron covalency.<sup>56</sup> Additionally there is σ-donation from O<sub>2</sub> to the d<sub>z<sup>2</sup></sub> orbital of iron. These interactions collectively weaken the O–O bond, resulting in a redshifted O–O stretch of 1159 cm<sup>-1</sup>, which is within the diagnostic range for superoxide.<sup>58</sup> This example illustrates the limitations of formal assignments in highly covalent metal–O<sub>2</sub> interactions and demonstrates that the O–O stretching frequency is not always sufficient to assign the degree of O<sub>2</sub> reduction definitively.<sup>59</sup> Furthermore, this result suggests targeting iron-based frameworks with highly covalent bonding between metal and linker as a strategy to achieve strong, reversible O<sub>2</sub> binding.

### 2.3 Superoxide (O<sub>2</sub><sup>-</sup>) complexes

Metal–O<sub>2</sub><sup>-</sup> complexes form upon transfer of a single electron from a reducing metal center (*e.g.*, Cr<sup>II</sup>, Mn<sup>I</sup>, Fe<sup>II</sup>, Ni<sup>I</sup>, and Cu<sup>I</sup>) into the half-filled π\* orbital of O<sub>2</sub>.<sup>52</sup> Population of this antibonding orbital weakens the π bond of O<sub>2</sub>, resulting in a modest elongation of the O–O distance from 1.21 to 1.29–1.35 Å, as well as a redshift of the O–O stretching mode from 1555 cm<sup>-1</sup> to 1050–1200 cm<sup>-1</sup> (Fig. 1b).<sup>23,60</sup> Superoxide may bind in either a side-on or an end-on mode. The end-on binding mode involves localization of negative charge on the proximal oxygen and a bent M–O–O angle. Side-on binding, while potentially more sterically demanding, can improve metal–superoxide orbital overlap. For both binding modes, the unpaired electron on superoxide resides in a π\* orbital, and magnetic coupling between the superoxide and metal center is determined by overlap of this orbital with half-filled metal d orbitals. For example, in an end-on d<sup>9</sup> copper(II) superoxide complex (Fig. 1b), the singly occupied d<sub>x<sup>2</sup>-y<sup>2</sup></sub>

orbital is orthogonal to the superoxide π\* non-bonding orbital, affording an *S* = 1 ground state that arises from ferromagnetic coupling between the metal and O<sub>2</sub><sup>-</sup>.<sup>61</sup>

The formation of end-on superoxide upon O<sub>2</sub> binding is also well-documented for five-coordinate cobalt(II) Schiff base complexes. Oxygen binding in solution results in the formation of a superoxide ion bound to cobalt(III), with enthalpies ranging from -33 to -77 kJ mol<sup>-1</sup>, and a corresponding high entropic penalty of >150 J mol<sup>-1</sup> K<sup>-1</sup>.<sup>24</sup> The oxygenation of cobalt(II) Schiff base complexes in solution is often reversible, although it is very dependent on solvent and temperature. Particularly at high temperature and in non-polar solvents, the formation of a Co<sup>III</sup><sub>2</sub>(μ<sup>2</sup>-O<sub>2</sub><sup>2-</sup>) species can occur, which is usually an irreversible process.<sup>24</sup> Another well-known Co<sup>III</sup>-O<sub>2</sub><sup>-</sup> complex is Co(TpivPP)(1-MeIm)(O<sub>2</sub>), a model for cobalt-substituted hemoglobin that reversibly binds O<sub>2</sub> (Table 3).<sup>58,62,63</sup>

### 2.4 Peroxide (O<sub>2</sub><sup>2-</sup>) complexes

In general, peroxide complexes form upon transfer of two electrons from one or more metal centers to fill the formerly half-occupied π\* orbitals of O<sub>2</sub>. In compounds featuring a metal prone to two-electron chemistry, such as titanium(II), manganese(II), or a second- or third-row transition metal, both electrons may derive from the same metal center.<sup>52</sup> Reduction of O<sub>2</sub> to peroxide is associated with significant lengthening of the O–O bond, from 1.21 to 1.40–1.50 Å, as well as a pronounced redshift in the O–O stretching mode to approximately 800–1050 cm<sup>-1</sup> (Fig. 1c).<sup>60</sup> In mononuclear complexes, peroxide tends to bind in a side-on fashion, as there is no efficient mechanism for polarizing the O<sub>2</sub><sup>2-</sup> charge on a single oxygen atom (Fig. 1c). One notable peroxide complex is oxyhemocyanin, which features a binuclear copper(II) core with a side-on bridging O<sub>2</sub><sup>2-</sup>.<sup>27</sup> This oxygen-binding protein has inspired the development of a diverse class of molecular mimics,<sup>50</sup> including [Cu<sub>2</sub>(N4PY2)(O<sub>2</sub>)]<sup>2+</sup> (N4 = N<sup>I</sup>,N<sup>I</sup>,N<sup>I</sup>,N<sup>I</sup>-tetrakis(2-(pyridin-4-yl)ethyl)butane-1,4-diamine), which binds O<sub>2</sub> reversibly in solution.<sup>64</sup> Interestingly, increasing temperature and decreasing O<sub>2</sub> pressure in the headspace of the reaction vessel enables repeated cycling between oxygenated and deoxygenated forms. This molecule binds O<sub>2</sub> *via* single-electron transfer from each copper(I), and this event is associated with an enthalpy of -58 kJ mol<sup>-1</sup> and an entropy of -165 J mol<sup>-1</sup> K<sup>-1</sup>, such that the reaction is exergonic at 298 K (Table 3).

Table 3 O<sub>2</sub> binding properties of notable biological and synthetic examples

## 2.5 Metal and ligand selection and secondary-sphere effects

As discussed above, reversible  $O_2$  binding at open metal sites can generate a spectrum of  $O_2$  species and binding modes. Further fine-tuning of  $O_2$  binding affinity can be accomplished by changing the metal identity in an isostructural series of compounds, perturbing the electronic structure of the metal *via* ligand modifications,<sup>61–63</sup> or by altering the steric and non-covalent interactions in the secondary coordination sphere (Fig. 2).<sup>33,49,65</sup> The first effect is well-illustrated by the series of complexes (TPP)M( $O_2$ )(py) (TPP = tetraphenylporphyrin; M = Cr<sup>II</sup>, Fe<sup>II</sup>, or Co<sup>II</sup>; py = pyridine), wherein the equilibrium constant for oxygenation increases from Co to Cr (Fig. 2a).<sup>66–69</sup> Indeed,  $O_2$  binding in Cr(TPP)(py) is irreversible, even at low temperatures.<sup>68</sup>

Examples of electronic structure perturbation by ligand modification abound for divalent first-row metal complexes.<sup>49,65,69–71</sup> In numerous cobalt(II) five-coordinate Schiff base and five-coordinate porphyrin complexes, cobalt adopts a low-spin,  $d^7$  configuration ( $S = 1/2$ ), with the unpaired electron residing in the  $d_{z^2}$  orbital.<sup>72–75</sup> Oxygen binds end-on to the metal site, mediated by a  $d_{z^2}-\pi^*$  orbital interaction that enables electron transfer.<sup>76</sup> It is possible to destabilize the  $d_{z^2}$  energy by changing the axial ligand, which lowers the potential for metal-centered oxidation, thereby increasing  $O_2$  affinity (Fig. 2b).<sup>49,65,76,77</sup> In addition, derivatization of the axial ligand can modify the  $\sigma$  and  $\pi$  bonding contributions to oxygen binding. Analogously, subtle modifications to the linker in cobalt(II) frameworks have been shown to give rise to substantial differences in  $O_2$  binding enthalpies (see Section 3.5).

Noncovalent interactions can also stabilize bound  $O_2$  or promote reversible  $O_2$  binding, as exemplified in several biomimetic systems,<sup>55,78–85</sup> and hydrogen bonding is known to stabilize the reduced  $O_2$  species bound in myoglobin and hemoglobin.<sup>70,86</sup> Additionally, incorporating steric bulk around the metal- $O_2$  adduct can stabilize reactive  $O_2$  intermediates. For example, iron(II)-porphyrin compounds undergo irreversible oxidation to form oxo-bridged dinuclear species in solution.<sup>87</sup> In contrast, the picket fence iron(II) porphyrin Fe<sup>II</sup>(TpivPP)(1-MeIm)<sub>2</sub> features substantial steric bulk around the metal center, which prevents bridge formation and enables reversible  $O_2$  binding at 25 °C (Fig. 2c).<sup>55</sup> More recent strategies combining steric protection with favorable non-covalent interactions have also proven fruitful. For example, single-coronet and twin-coronet iron(II) porphyrins featuring hydroxyl-functionalized dinaphthalene moieties have been designed to replicate the hydrophobic environment of the active sites in hemoglobin and myoglobin and to promote biomimetic hydrogen bonding interactions with bound  $O_2$ .<sup>82,83</sup> Despite their ubiquity in biology and small molecule chemistry, secondary sphere interactions remain underutilized in MOF chemistry and represent a worthwhile target for future research in the design of  $O_2$ -selective materials.<sup>88</sup>

## 2.6 Lessons from biology: cooperative $O_2$ binding

Hemoglobin is the prototypical iron-containing  $O_2$  transport protein and features four subunits, with each containing a heme active site.<sup>89,90</sup> The heme iron(II) center is a five-coordinate species with the fifth site occupied by an axial

Fig. 2 Illustration of design strategies from molecular chemistry to enhance  $O_2$  binding affinity. (a) Utilizing early- to mid-transition metals,<sup>67–69</sup> (b) increasing the ligand field strength,<sup>71</sup> and (c) using bulky side groups that engage in stabilizing non-covalent interactions with the reduced  $O_2$  species.<sup>55,67,82</sup> Axial solvent ligands are omitted for clarity; in the single coronet iron porphyrin (top right), the distal two naphthalene molecules have been modified for simplicity.

histidine ligand, resulting in a high spin ( $S = 2$ ) ground state. Dioxygen binds the first heme site with an enthalpy of  $-43.1 \text{ kJ mol}^{-1}$ , yielding a diamagnetic species with an end-on bound  $\text{O}_2$ .<sup>91</sup> A recent study of oxyhemoglobin using X-ray spectroscopy and a valence bond configuration interaction multiplet model revealed mixed low spin  $\text{Fe}^{\text{II}}/\text{Fe}^{\text{III}}$  character with at least 50% iron(III), reflecting a highly covalent  $\text{Fe}-\text{O}_2$  interaction.<sup>57</sup> The change in the iron(II) spin state upon  $\text{O}_2$  binding is associated with the depopulation of iron-based orbitals with  $\sigma^*$  character, resulting in a contraction of the iron–nitrogen bonds. This local structural change is propagated to the global protein structure *via* the axial histidine, effecting a transition from the so-called ‘tense’ state (low  $\text{O}_2$  affinity) to the ‘relaxed’ state (high  $\text{O}_2$  affinity).<sup>89</sup> This change facilitates subsequent  $\text{O}_2$  binding events at the other heme sites. For example,  $\text{O}_2$  binding to the fourth heme is associated with an enthalpy of  $-85.0 \text{ kJ mol}^{-1}$  (Table 3).<sup>91</sup> This cooperativity is key to the function of hemoglobin, enabling the capture and release of relatively large quantities of  $\text{O}_2$  in response to a small change in oxygen partial pressure, and is associated with a sigmoidal  $\text{O}_2$  binding curve. An unrealized goal in the design of  $\text{O}_2$ -selective MOFs is to harness cooperativity to enhance material working capacities for  $\text{O}_2$  separations, an approach that has proven to be effective for other gaseous adsorbents, including  $\text{CO}_2$  and  $\text{CO}$ .<sup>92,93</sup> As discussed below (see Section 3.4), a triazolate-based framework featuring high-spin iron(II) has been shown to react with  $\text{O}_2$  to form low-spin iron(III) bound to superoxide, reminiscent of the mechanism of  $\text{O}_2$  binding in hemoglobin.<sup>45</sup> As such, further exploration of the reduction of  $\text{O}_2$  to superoxide by iron-containing MOFs of different topologies may be a fruitful direction in pursuit of cooperative  $\text{O}_2$  binding in MOFs.

### 3. Oxygen-selective metal–organic frameworks

#### 3.1 Enthalpy and entropy considerations for $\text{O}_2$ adsorbents

The enthalpy of  $\text{O}_2$  binding at an open metal site is a critical parameter for evaluating the adsorption performance of a material. Indeed, the energy consumption of an adsorption process depends heavily on the enthalpy of adsorption, and in some cases, the enthalpy can represent half of the total energy required for adsorbent regeneration.<sup>94</sup> As such, the  $\text{O}_2$  binding enthalpy is a critical metric to optimize in the design of a commercially relevant  $\text{O}_2$ -selective MOF, and one that can be judiciously tuned using synthetic chemistry. Perhaps unsurprisingly, there has been a historical focus on this particular parameter. In general, the lower the  $\text{O}_2$  binding enthalpy of a material, the lower the corresponding energy demand for adsorbent regeneration. However, if the enthalpy of  $\text{O}_2$  binding is too low, the material may not exhibit sufficient selectivity for  $\text{O}_2$  over  $\text{N}_2$ .

The enthalpy of  $\text{N}_2$  binding at open metal sites has been experimentally determined for a number of frameworks<sup>44,45,95,96</sup> with corresponding values typically ranging from  $-10$  to  $-25 \text{ kJ mol}^{-1}$  (*vs.*  $\Delta H = -22.5 \text{ kJ mol}^{-1}$  for Li-LSX<sup>97</sup>). Accordingly, candidate MOFs for  $\text{O}_2$ -selective air separations should

ideally exhibit  $\text{O}_2$  binding enthalpies well above this range. However, materials that exhibit  $\text{O}_2$  binding enthalpies that surpass  $-80 \text{ kJ mol}^{-1}$  may not afford any energy savings over the current industrial benchmark,  $\text{N}_2$ -selective Li-LSX, due to the energy required to regenerate the  $\text{O}_2$  adsorbent (see ESI Section S2†). Thus, to provide a baseline for analysis, we propose  $-45 \text{ kJ mol}^{-1}$  as a reasonable target  $\text{O}_2$  binding enthalpy, which would correspond to a material regeneration energy that is  $\sim 50\%$  less than that required for Li-LSX.<sup>28,97</sup> While an even higher enthalpy of adsorption is likely to be associated with greater  $\text{O}_2/\text{N}_2$  selectivity, it would come at the cost of greater energy demand for regeneration.

While the enthalpy of  $\text{O}_2$  binding is a key factor that will impact the overall energy of adsorbent-based air separations, this parameter must be considered together with the entropy of adsorption. Indeed, it is  $\Delta G$ , and not  $\Delta H$  alone, that determines the adsorption properties of a material. In particular,  $\Delta G$  for the primary  $\text{O}_2$  binding site will determine the working capacity under a given set of conditions.<sup>98</sup> This information is necessary to establish the potential performance of the material in an adsorptive process (see Section 3.5). As such, a binding enthalpy of  $-45 \text{ kJ mol}^{-1}$  is desirable as long as the corresponding entropy of binding results in an appropriate  $\Delta G$  for the adsorption process. Relative to binding enthalpy, it is much more difficult to tune the entropy of  $\text{O}_2$  binding *via* metal and/or linker modifications. Entropies of adsorption are not typically reported in the literature, and currently there is no consistent method for reporting both  $\Delta H$  and  $\Delta S$  for  $\text{O}_2$ -selective adsorbents.<sup>99</sup> As such, to enable a more rigorous comparison of materials in this Perspective, we calculated enthalpy and entropy values for several key  $\text{O}_2$ -selective frameworks using published Langmuir–Freundlich fits or  $\text{O}_2$  adsorption data (see ESI Sections S4 and S5 for details and Tables S1–S9†).<sup>44–47,88</sup> More generally, we suggest that routine determination of binding enthalpies and entropies is a critical facet of materials characterization, requiring minimal additional work, that will enable more rigorous development and benchmarking of MOFs for practical application.

#### 3.2 Key framework structure types

Despite the effectively limitless structural variability possible for metal–organic frameworks, a relatively limited number of frameworks have been studied for selective  $\text{O}_2$  adsorption. Here, we briefly describe six key framework structure types that have been studied for selective  $\text{O}_2$  capture (Fig. 3).

**3.2.1  $\text{M}_2(\text{dobdc})$ .** The  $\text{M}_2(\text{dobdc})$  ( $\text{M} = \text{Mg}^{\text{II}}, \text{Mn}^{\text{II}}, \text{Fe}^{\text{II}}, \text{Co}^{\text{II}}, \text{Ni}^{\text{II}}, \text{Cu}^{\text{II}}, \text{Zn}^{\text{II}}$ ;  $\text{dobdc}^{4-} = 2,5\text{-dioxido-1,4-benzenedicarboxylate}$ ; MOF-74, CPO-27)<sup>95,100–103</sup> family of frameworks features one-dimensional hexagonal pores with vertices lined by helical chains of coordinatively unsaturated divalent metal centers (Fig. 3a). The metals exhibit a square pyramidal coordination geometry, with open coordination sites facing into the pore interior, and are ligated by weak-field carboxylate and aryloxy ligands. These frameworks are particularly attractive, owing to their facile syntheses, tunability, and high density of open metal sites ( $6.54 \text{ mmol g}^{-1}$  in the case of  $\text{Fe}_2(\text{dobdc})$ , Table 4). Oxygen

Fig. 3 Representative structures obtained from powder X-ray diffraction (a, b, e), powder neutron diffraction (c, d), or single-crystal X-ray diffraction (f) depicting the six MOF structure types discussed in Section 3.2. Insets show the first coordination sphere of each open metal site. (a)  $\text{Fe}_2(\text{dobdc})$ ,<sup>43</sup> (b)  $\text{Co}_2\text{Cl}_2(\text{bbta})$ ,<sup>88</sup> (c)  $\text{Cu}^1\text{-MFU-4l}$ ,<sup>110</sup> (d)  $\text{Cu}_3(\text{btc})_2$ ,<sup>115</sup> (e)  $\text{Fe-BTTri}$ ,<sup>124</sup> and (f)  $\text{Mn-PCN-224}$ .<sup>47</sup> Orange, purple, green, pink, grey, red, and blue spheres represent Fe, Co, Cu, Mn, C, O, and N atoms, respectively; H atoms are omitted for clarity.

adsorption has been studied in the  $\text{Mn}^{2+}$ ,  $\text{Fe}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$  and  $\text{Cu}^{2+}$  variants of  $\text{M}_2(\text{dobdc})$ .<sup>43,95,96</sup>

**3.2.2  $\text{M}_2\text{X}_2(\text{bbta})$ .** Analogous to  $\text{M}_2(\text{dobdc})$ , the  $\text{M}_2\text{X}_2(\text{bbta})$  ( $\text{M} = \text{Mn}^{\text{II}}$ ,  $\text{Fe}^{\text{II}}$ ,  $\text{Co}^{\text{II}}$ ,  $\text{Ni}^{\text{II}}$ ;  $\text{X} = \text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{F}^-$ ,  $\text{OH}^-$ ;  $\text{H}_2\text{bbta} = 1H,5H\text{-benzo}(1,2\text{-}d:4,5\text{-}d')$ bistriazole) structure type<sup>88,93,104–107</sup> also features one-dimensional hexagonal channels with pore vertices lined by coordinatively-unsaturated, square pyramidal

$\text{M}^{\text{II}}$  sites. However, the primary metal coordination sphere is occupied by two basal and one apical triazolite ligands and two  $\mu^2$ -halide or hydroxide ligands (Fig. 3b). Several expanded-pore analogues of this family have also been developed—including the recently reported vanadium variant<sup>41</sup>—of the type  $\text{M}_2\text{Cl}_2(\text{btdd})$  ( $\text{H}_2\text{btdd} = \text{bis}(1H\text{-}1,2,3\text{-triazolo}[4,5\text{-}b],[4',5'\text{-}l])\text{dibenzo}[1,4]\text{dioxin}$ ).<sup>105,108</sup> While only  $\text{Co}_2\text{X}_2(\text{bbta})$  ( $\text{X} = \text{Cl}^-$  and  $\text{OH}^-$ ) has

Table 4 Theoretical and experimental  $\text{O}_2$  capacities, IAST  $\text{O}_2/\text{N}_2$  selectivities, reported binding enthalpies, and reported O–O infrared stretching frequencies for selected metal–organic frameworks, organized from highest to lowest binding enthalpy

<sup>a</sup> Calculated based on gravimetric density of open metal sites. <sup>b</sup> For Cr-BTT,  $\text{Cr}_3(\text{btc})_2$ , and  $\text{Fe}_2(\text{dobdc})$ , reported uptakes in wt% were converted to  $\text{mmol g}^{-1}$ ; all other framework capacities were reported in  $\text{mmol g}^{-1}$  and converted to wt%. <sup>c</sup> Stretching frequencies reported at temperatures associated with reversible  $\text{O}_2$  binding.

been studied for O<sub>2</sub> separations,<sup>88</sup> the tunability and metal site density of this material class render it a promising target for further exploration. As an example, the metal site density of Co<sub>2</sub>(OH)<sub>2</sub>(bbta) is 6.45 mmol g<sup>-1</sup>, comparable to the M<sub>2</sub>(dobdc) series (Table 4).

**3.2.3 M-MFU-4l.** The framework MFU-4l, or Zn<sub>5</sub>Cl<sub>4</sub>(btdd)<sub>3</sub>, features pentanuclear zinc nodes, each bridged by btdd<sup>2-</sup> linkers to six other nodes, resulting in three-dimensional pore system with square pore openings.<sup>109</sup> An octahedral zinc(II) ion sits at the center of each pentanuclear node, and four tetrahedral zinc(II) sites capped by terminal chloride ligands occupy the periphery. Approximately two of these four tetrahedral zinc sites can be post-synthetically exchanged with other divalent metals to yield M<sup>II</sup>-MUF-4l (M = Mn, Fe, Co, Ni, and Cu).<sup>110</sup> Reduction of Cu<sup>II</sup>-MFU-4l yields Cu<sup>I</sup>-MFU-4l, which features trigonal pyramidal copper(I) sites (Fig. 3c).<sup>46</sup> Although their density is low (1.69 mmol g<sup>-1</sup>), these open copper(I) sites interact strongly ( $\Delta H = -52.6(6)$  kJ mol<sup>-1</sup>) and reversibly with O<sub>2</sub>. Interestingly, a recent investigation of O<sub>2</sub> binding in Cu<sup>I</sup>-MFU-4l using near-edge X-ray absorption fine structure spectroscopy and DFT revealed that the interaction between copper(I) and O<sub>2</sub> is highly covalent, and that O<sub>2</sub> most likely binds side on at the metal site in its triplet configuration.<sup>111</sup> Given the high tunability<sup>110,112,113</sup> of this structure type, it could serve as an excellent platform to optimize O<sub>2</sub> binding through ligand modification, as an example. We note that the isorecticular framework MFU-4, or Zn<sub>5</sub>Cl<sub>4</sub>(bbta)<sub>3</sub>, is known,<sup>114</sup> and although it has not been demonstrated, if the peripheral Zn<sup>II</sup>-Cl units in the structure can be replaced with Cu<sup>I</sup>, then the corresponding material could exhibit a significantly greater O<sub>2</sub> capacity than Cu<sup>I</sup>-MFU-4l.

**3.2.4 M<sub>3</sub>(btc)<sub>2</sub>.** As discussed above, the first MOF investigated for O<sub>2</sub> adsorption was Cr<sub>3</sub>(btc)<sub>2</sub>,<sup>42</sup> which belongs to a larger family of M<sub>3</sub>(btc)<sub>2</sub> materials (also known as M-HKUST-1; M = Cr<sup>II</sup>, Fe<sup>II</sup>, Ni<sup>II</sup>, Cu<sup>II</sup>, Zn<sup>II</sup>, Mo<sup>II</sup>, Ru<sup>II</sup>).<sup>115-122</sup> This cubic framework structure features dinuclear paddlewheel-type nodes, each coordinated by four carboxylate groups provided by the triangular trimesate linkers. Each exposed metal site from each paddlewheel node points into a cavity and is accessible to guest molecules (Fig. 3d). This structure class also features a high density of open metal sites (6.43 mmol g<sup>-1</sup> for Cr<sub>3</sub>(btc)<sub>2</sub>, Table 4). To date, Cr<sub>3</sub>(btc)<sub>2</sub> is the only material studied for selective O<sub>2</sub> uptake in this family. However, solvated Fe<sub>3</sub>(btc)<sub>2</sub> has been isolated and structurally characterized,<sup>122</sup> and the permanently porous and fully desolvated framework represents an interesting candidate for further study.

**3.2.5 M-Benzenetrisazolates.** The frameworks Cr<sub>3</sub>[(Cr<sub>4</sub>-Cl)<sub>3</sub>(BTT)<sub>8</sub>]<sub>2</sub> (Cr-BTT; H<sub>3</sub>BTT = 1,3,5-tri(1*H*-tetrazol-5-yl)benzene),<sup>123</sup> M<sub>3</sub>[(M<sub>4</sub>Cl)<sub>3</sub>(BTTri)<sub>8</sub>]<sub>2</sub> (M-BTTri; M = Fe<sup>II</sup>, Co<sup>II</sup>; H<sub>3</sub>BTTri = 1,3,5-tri(1*H*-1,2,3-triazol-5-yl)benzene),<sup>44,45,124</sup> and Co<sub>3</sub>[(Co<sub>4</sub>Cl)<sub>3</sub>(BDTriP)<sub>8</sub>]<sub>2</sub> (Co-BDTriP; H<sub>3</sub>BDTriP = 5,5'-(5-(1*H*-pyrazol-4-yl)-1,3-phenylene)bis(1*H*-1,2,3-triazole))<sup>44</sup> are O<sub>2</sub> adsorbents belonging to a large family of cubic M-benzenetrisazolate MOFs (Fig. 3e) with open metal site densities close to 4 mmol g<sup>-1</sup> (Table 4).<sup>125-127</sup> These sodalite-type structures are built up of truncated octahedra with square nodes formed by four M<sup>2+</sup> centers bridged by a central μ<sup>4</sup>-Cl and triangular faces

formed by benzenetrisazolate linkers. These frameworks are anionic and are charge-balanced by three extra-framework M<sup>II</sup> ions per formula unit. Each square pyramidal metal center is coordinated by four basal azolate nitrogen atoms and one apical chloride. The material Co-BDTriP is unique in that it features a distribution of cobalt(II) sites bound by a combination of pyrazolates and triazolates.<sup>44</sup> Notably, Cr-BTT exhibits one of the highest O<sub>2</sub> capacities of any framework studied to date, 7.6 wt% at 298 K and 1 bar.<sup>123</sup>

**3.2.6 M-PCN-224.** The M-PCN-224 frameworks (M = Mn<sup>II</sup>, Fe<sup>II</sup>, Co<sup>II</sup>, Ni<sup>II</sup>, Cu<sup>II</sup>) consist of zirconium cluster nodes connected by tetratopic porphyrin linkers in a cubic architecture.<sup>47,128-132</sup> The composition of these frameworks is highly variable depending on the synthetic conditions used, and as such it is not straightforward to specify one representative chemical formula. However, a recent study demonstrated that different post-synthetic treatments of the as-synthesized precursor PCN-224 (ref. 133) yield well-defined structures (H<sub>2</sub>-tcpp)<sub>3</sub>[Zr<sub>6</sub>O<sub>4</sub>(OH)<sub>4</sub>(CH<sub>3</sub>CO<sub>2</sub>)<sub>6</sub>]<sub>2</sub> or (H<sub>2</sub>tcpp)<sub>3</sub>[Zr<sub>6</sub>O<sub>4</sub>(μ-OH)<sub>4</sub>(OH)<sub>6</sub>]<sub>2</sub> (H<sub>2</sub>tcpp = 5,10,15,20-tetrakis(4-carboxyphenyl)porphyrin). For simplicity, in the subsequent discussion and calculations, we assume a formula of M<sub>3</sub>(tcpp)<sub>3</sub>[Zr<sub>6</sub>O<sub>4</sub>(μ-OH)<sub>4</sub>(OH)<sub>6</sub>]<sub>2</sub> for the M-PCN-224 frameworks. Of the frameworks studied to date, the Mn<sup>II</sup>, Fe<sup>II</sup>, and Co<sup>II</sup> variants have been shown to selectively adsorb O<sub>2</sub>. The isolated four-coordinate square planar metal centers in M-PCN-224 (Fig. 3f) mimic metalloporphyrin active sites in proteins, including hemoglobin and myoglobin. As the framework structural rigidity precludes binuclear decomposition pathways encountered with molecular compounds, these frameworks serve as important model systems for O<sub>2</sub> binding in biological systems. However, these MOFs exhibit the lowest metal site densities among the materials considered here (approximately 0.73 mmol g<sup>-1</sup>).

### 3.3 Tuning O<sub>2</sub> binding through ligand modification

Typically, MOFs that feature open metal sites are constructed using weak-field linkers, such as 2,5-dioxido-1,4-benzenedicarboxylate.<sup>100,133</sup> As such, the metal nodes are best described as Lewis acidic<sup>134</sup> and generally interact weakly with oxygen.<sup>95</sup> A telling example is Co<sub>2</sub>(dobdc), which remains high-spin when bound to CO, and exhibits an O<sub>2</sub> binding enthalpy of just -18.56(3) kJ mol<sup>-1</sup>.<sup>96</sup> As discussed in Section 2, strong oxygen binding in molecular cobalt complexes is well documented,<sup>49</sup> but it was only in 2016 that a cobalt(II)-based framework with a stronger ligand field than Co<sub>2</sub>(dobdc) was reported. The material Co-BTTri exhibits a modest O<sub>2</sub> adsorption enthalpy of -34(1) kJ mol<sup>-1</sup> (Table 4) for loadings up to ~2 mmol g<sup>-1</sup> (6 wt%).<sup>44</sup> Vibrational modes corresponding to the O<sub>2</sub> adduct could not be observed at room temperature, but calculations suggest there is only partial electron transfer from cobalt(II) to O<sub>2</sub> (0.31 electron equivalents). The theoretical uptake of the material, assuming one bound O<sub>2</sub> at each low-spin cobalt(II) site, is 3.86 mmol g<sup>-1</sup> (11.0 wt%); however, the experimental uptake at the cobalt sites was approximately 2.8 mmol g<sup>-1</sup> (8.2 wt%), as determined from the inflection point in the plot of the isosteric heat of adsorption as a function of loading. This

lower than expected capacity is common in frameworks with open metal sites and may be due to the presence of residual coordinated synthesis solvent or blocked pore access<sup>135</sup> or potentially even metal site vacancies.<sup>136,137</sup> Interestingly, the N<sub>2</sub> enthalpy of adsorption in Co-BTtri is only  $-12(1)$  kJ mol<sup>-1</sup>,<sup>44</sup> and this relatively weak affinity for N<sub>2</sub> suggests that the low-spin cobalt(II) sites are neither strongly Lewis acidic or  $\pi$ -basic.

Replacement of the triangular BTtri<sup>3-</sup> linker with the more basic BDTriP<sup>3-</sup>, which features one pyrazolate and two triazolate donors, yields the framework Co-BDTriP.<sup>44</sup> Characterization of this material *via* single-crystal X-ray diffraction supports the presence of a statistical distribution of five unique cobalt centers coordinated by a combination of triazolates and pyrazolates. Notably, at very low loadings, the isosteric heat of O<sub>2</sub> adsorption in Co-BDTriP is  $-47(1)$  kJ mol<sup>-1</sup>, corresponding to O<sub>2</sub> bound at approximately 12% of the cobalt(II) sites in the material. This enthalpy is much larger than the highest binding enthalpy characterized for Co-BTtri (and within the range observed for cobalt(II) Schiff complexes, see Section 2.3), and was ascribed to O<sub>2</sub> binding at cobalt sites ligated by three or more pyrazolates. Relative to the enthalpy of O<sub>2</sub> binding in Co-BTtri at low-loading, this larger value can be rationalized as arising from a greater degree of charge transfer from cobalt(II) to O<sub>2</sub>, resulting from the more basic (electron-donating) pyrazolate groups. With increasing gas loading, the enthalpy of O<sub>2</sub> binding in Co-BDTriP decreases, and at a loading of approximately 1 mmol g<sup>-1</sup>, Co-BDTriP and Co-BTtri exhibit similar binding enthalpies. Interestingly, increasing the linker basicity from Co-BTtri to Co-BDTriP has little effect on the enthalpy of N<sub>2</sub> adsorption. The more basic linker environment in Co-BDTriP may destabilize the d<sub>z<sup>2</sup></sub> orbital of cobalt(II) relative to that in Co-BTtri, yielding a less Lewis-acidic metal center and thereby diminishing the  $\sigma$  interaction between the HOMO of N<sub>2</sub> and cobalt, compensating for any enhanced  $\pi$ -backbonding. Considering the enhancement in O<sub>2</sub> binding enthalpy at low loadings upon moving from Co-BTtri to Co-BDTriP, a promising target may be the material Co<sub>3</sub>[(Co<sub>4</sub>X)<sub>3</sub>(BTP)<sub>8</sub>]<sub>2</sub> (hereafter, *Co-BTP*, H<sub>3</sub>BTP = 1,3,5-tri(1*H*-pyrazol-4-yl)benzene), featuring all pyrazolate donors. Such a material isostructural to Co-BTtri and Co-BDTriP has not yet been isolated, although the framework Co<sub>3</sub>(BTP)<sub>2</sub> has previously been synthesized,<sup>138</sup> suggesting that appropriate synthetic conditions may yield *Co-BTP*. In general, the results for Co-BTtri and Co-BDTriP indicate that further investigation of suitable frameworks featuring basic azolate-based linkers and cobalt(II) centers is a worthwhile pursuit.

The open metal sites in Co<sub>2</sub>Cl<sub>2</sub>(bbta) exhibit a square pyramidal metal coordination geometry, similar to that in Co-BTtri and Co-BDTriP. However, the metal sites are ligated by two *trans* basal chloride ions and three triazolates (Fig. 3b).<sup>105</sup> The O<sub>2</sub> binding enthalpy of  $-15$  kJ mol<sup>-1</sup> in Co<sub>2</sub>Cl<sub>2</sub>(bbta)<sup>88</sup> is significantly lower than in Co-BTtri and Co-BDTriP, and perhaps surprisingly, even lower than in Co<sub>2</sub>(dobdc). Here, the replacement of a strong  $\sigma$ -donating nitrogen ligand with a weakly  $\sigma$ -donating chloride likely attenuates metal-to-oxygen charge transfer, and thus the cobalt(II) sites in Co<sub>2</sub>Cl<sub>2</sub>(bbta) are both insufficiently reducing and poor Lewis acids.

Replacing the bridging chlorides in Co<sub>2</sub>Cl<sub>2</sub>(bbta) with more basic hydroxides yields the material Co<sub>2</sub>(OH)<sub>2</sub>(bbta).<sup>106</sup> This framework exhibits an O<sub>2</sub> binding enthalpy of  $-49(2)$  kJ mol<sup>-1</sup> at low loadings, the highest value reported to date for a cobalt framework.<sup>88</sup> *In situ* variable-temperature diffuse reflectance Fourier transform spectroscopy (DRIFTS) was used to characterize the O<sub>2</sub> binding and revealed an O–O stretch at 1151 cm<sup>-1</sup>, consistent with a superoxide moiety bound end-on to cobalt(III). DRIFTS data also indicate that the superoxide is stabilized by hydrogen bonding interactions with the bridging hydroxo groups of the framework, reminiscent of the stabilization of superoxide in oxygen binding proteins. Calculations suggest that this secondary coordination lowers the binding energy of O<sub>2</sub> by 20 kJ mol<sup>-1</sup>, highlighting the significant impact of subtle coordination sphere changes in isostructural MOFs. This additional interaction also contributes to a very large entropy of adsorption of  $-186(7)$  J mol<sup>-1</sup> K<sup>-1</sup>.

Interestingly, the calculated saturation capacity of the strong O<sub>2</sub> binding site in Co<sub>2</sub>(OH)<sub>2</sub>(bbta)—determined from fits using a dual-site Langmuir model—was found to be 2.46 mmol g<sup>-1</sup>, only 38% of the theoretical capacity based on open metal site density. However, data from powder X-ray diffraction analysis revealed that the actual occupancy is much higher (approximately 75%), indicating that the chosen adsorption model was not adequate for describing the O<sub>2</sub> uptake in this material. Together with *in situ* DRIFTS data obtained at different O<sub>2</sub> loadings, these results revealed that O<sub>2</sub> binding weakens as a function of loading, a rare example of negatively cooperative gas binding in a metal-organic framework.<sup>139</sup> Notably, the same extended lattice interactions that promote initial strong O<sub>2</sub> binding contribute to this unusual effect. Indeed, with increasing O<sub>2</sub> loading, the proportion of cobalt(III)–O<sub>2</sub><sup>-</sup> moieties also increases, rendering neighboring cobalt(II) sites less electron-donating and therefore less likely to bind O<sub>2</sub> *via* electron transfer. This unexpected result highlights that the nature of electronic communication between metal sites in MOFs must be tuned carefully to achieve desired O<sub>2</sub> binding properties. Here, the appropriate choice of a secondary metal could potentially give rise to an ordered mixed-metal framework of the type CoM(OH)<sub>2</sub>(bbta) that exhibits a high enthalpy of O<sub>2</sub> binding in the absence of negative cooperativity. In this case, it may be possible to achieve an O<sub>2</sub> uptake as high as 3 mmol g<sup>-1</sup>. However, due to the presence of hydrogen bonding interactions, even in this case, O<sub>2</sub> binding is still likely to be associated with a high entropic penalty. As an alternative, replacing the hydroxide moieties with bridging methoxide or methylthiolate anions would remove such interactions and potentially still provide sufficient reducing power at the metal center to ensure a high binding enthalpy.

### 3.4 Tuning O<sub>2</sub> binding through metal selection

One of the most well-studied isostructural framework series is M<sub>2</sub>(dobdc) (M = Mn<sup>II</sup>, Fe<sup>II</sup>, Co<sup>II</sup>, Ni<sup>II</sup>, Cu<sup>II</sup>, Zn<sup>II</sup>).<sup>133</sup> Excluding the iron variant, the open metal sites in this family behave like Lewis acids, and generally, they preferentially bind N<sub>2</sub> over O<sub>2</sub>,<sup>43,95,96</sup> given the greater polarizability and quadrupole

moment of N<sub>2</sub> (Table 1).<sup>97</sup> Characterization of O<sub>2</sub> binding in the Mn, Co, Ni, and Cu variants revealed that the metal–O<sub>2</sub> interactions are also predominately electrostatic in nature.<sup>95,96</sup>

The case of O<sub>2</sub> binding in Fe<sub>2</sub>(dobdc) is unique and can be partly rationalized by the fact that iron(II) exhibits a lower ionization energy than Mn<sup>II</sup>, Co<sup>II</sup>, Ni<sup>II</sup>, and Cu<sup>II</sup>. Uptake of O<sub>2</sub> in Fe<sub>2</sub>(dobdc) results in very steep adsorption isotherm and occurs *via* superoxide or peroxide formation, depending on the temperature.<sup>43</sup> At 211 K, ~90% of the iron sites reversibly bind O<sub>2</sub>, with a total uptake for the material of 6.54 mmol g<sup>-1</sup> (17.3 wt%) at 1 bar. Notably, the material is stable to repeated cycling and exhibits no loss in capacity at 211 K over the course of at least 13 adsorption/desorption cycles. The enthalpy of O<sub>2</sub> adsorption in this material was calculated to be -41 kJ mol<sup>-1</sup>. Although this value is lower than the binding enthalpy determined for Co<sub>2</sub>(OH)<sub>2</sub>(bbta), the associated O<sub>2</sub> moiety in Fe<sub>2</sub>(dobdc) is more reduced than that bound in Co<sub>2</sub>(OH)<sub>2</sub>(bbta), as judged from their respective O–O stretches of 1129 and 1151 cm<sup>-1</sup> (Table 4). The enhanced stabilization of bound O<sub>2</sub> in Co<sub>2</sub>(OH)<sub>2</sub>(bbta) relative to Fe<sub>2</sub>(dobdc) can again be ascribed to the substantial enthalpic contribution from hydrogen bonding (as discussed above). At room temperature, O<sub>2</sub> binding in Fe<sub>2</sub>(dobdc) results in irreversible formation of iron(III)–peroxide species at half of the iron sites, with the second reducing equivalent provided by the remaining iron sites. As expected, the O–O bond of the reduced moiety is substantially weakened, and a very low O–O stretch of 790 cm<sup>-1</sup> was characterized *via* IR spectroscopy. The ordered substitution of 50% or more of the iron(II) sites in Fe<sub>2</sub>(dobdc) with another divalent metal could potentially suppress the electron transfer between metal sites that leads to irreversible peroxide formation and enable access to a material exhibiting high, reversible O<sub>2</sub> uptake. Of note, while metal–metal communication in Fe<sub>2</sub>(dobdc) has a deleterious effect on O<sub>2</sub> uptake, it is interesting to consider how the participation of two adjacent metal sites in one reduction and binding event, as observed here, could be manipulated *via* linker and secondary-sphere interactions to achieve positive cooperativity in O<sub>2</sub> binding.

The framework Fe-BTTri was recently reported, enabling preliminary evaluation of the influence of metal identity on O<sub>2</sub> binding in M-BTTri. Interestingly, the local iron coordination environment in this material bears some resemblance to the heme site of hemoglobin.<sup>45</sup> At 195 K, 64% of the exposed high-spin iron(II) framework sites bind O<sub>2</sub> *via* superoxide formation with an enthalpy of -51 kJ mol<sup>-1</sup>, which is 1.5 times that of the binding enthalpy in Co-BTTri. The material reversibly adsorbs 3.3 mmol g<sup>-1</sup> (9.6 wt%) of O<sub>2</sub> at 195 K and 210 mbar over the course of 5 cycles. *In situ* DRIFTS data obtained at 195 K revealed an O–O stretch at 1199 cm<sup>-1</sup>, which, together with Mössbauer data, confirms the presence of superoxide bound to low-spin iron(III), reminiscent of the mechanism of O<sub>2</sub> binding in hemoglobin (Section 2.6). This complete electron transfer from iron(II) to O<sub>2</sub> contrasts with the partial electron transfer upon O<sub>2</sub> binding in Co-BTTri. Above 258 K, O<sub>2</sub> binding is irreversible.

The M-PCN-224 (M = Mn<sup>II</sup>, Fe<sup>II</sup>, Co<sup>II</sup>) framework class is another instructive example to evaluate the importance of metal

identity for O<sub>2</sub> binding in MOFs.<sup>47,129,130</sup> In contrast to what is observed for M<sub>2</sub>(dobdc), the enthalpy of O<sub>2</sub> binding in M-PCN-224 increases from cobalt to iron to manganese, consistent with the general trend observed for metalloporphyrin complexes (Section 2). Note, however, that O<sub>2</sub> binding to Mn-PCN-224 (ref. 47) is a two-electron process, whereas one-electron reduction occurs upon O<sub>2</sub> uptake in the other two frameworks. In Mn-PCN-224, 85% of the manganese(II) sites bind O<sub>2</sub> with an enthalpy of -49.6(8) kJ mol<sup>-1</sup>. The resulting adduct is an η<sup>2</sup>-peroxomanganese(IV), and the reaction is reversible upon purging with argon.

The framework Fe-PCN-224 (ref. 129) provides a rare example of a base-free heme model. In this material, the high-spin ferrous centers bind O<sub>2</sub> at 195 K to form low-spin iron(III)–superoxo moieties, as characterized using single-crystal X-ray diffraction and Mössbauer spectroscopy data collected at 100 K. Oxygen binding is only appreciable at 195 K and below, and from low-temperature (141, 156, and 195 K) isotherm data the O<sub>2</sub> binding enthalpy was determined to be -34(4) kJ mol<sup>-1</sup>, consistent with the formation of a superoxo moiety. Notably, this value is substantially lower than that associated with O<sub>2</sub> binding in hemoglobin as well as in biomimetic compounds that feature a bound axial imidazole.<sup>51,91</sup> Using reported isotherm data obtained at higher temperatures (226, 273, and 298 K), we calculated an even lower binding enthalpy of -19(2) kJ mol<sup>-1</sup>. The large difference in the enthalpy values for the given temperature regimes suggests that binding of O<sub>2</sub> at and near room temperature is associated with the formation of an iron–O<sub>2</sub> adduct distinct from that observed at lower temperatures. In all, these data suggest that electron transfer from iron to O<sub>2</sub> in this system is temperature-dependent, and further studies are warranted to investigate this possibility.

Dioxygen binding in Co-PCN-224 (ref. 130) results in the formation of a low-spin Co<sup>III</sup>–superoxide complex, as characterized *via* single-crystal X-ray diffraction and EPR spectroscopy performed at 85 K. Oxygen adsorption data collected at higher temperatures (113, 141, 156, and 195 K) were used to calculate an enthalpy of O<sub>2</sub> binding of -15.2(6) kJ mol<sup>-1</sup>, which is much lower than that associated with superoxide formation in Co(TpivPP)(1-MeIm) (Table 3). It is possible that at the higher temperatures associated with isotherm data collection, O<sub>2</sub> binding results in a Co<sup>II</sup>–O<sub>2</sub> species. Indeed, an enthalpy of -15.2(6) kJ mol<sup>-1</sup> is more consistent with reported enthalpies of -15 and -18.56(3) kJ mol<sup>-1</sup> associated with the formation of Co<sup>II</sup>–O<sub>2</sub> adducts in Co<sub>2</sub>Cl<sub>2</sub>(bbta)<sup>88</sup> and Co<sub>2</sub>(dobdc),<sup>96</sup> respectively. In all, the above results suggest that the detailed investigation of O<sub>2</sub> binding modes in Fe-PCN-224 and Co-PCN-224 as a function of temperature, including the determination of enthalpies and entropies, represents a worthwhile fundamental study.

### 3.5 Evaluating optimal ΔG for O<sub>2</sub>-selective adsorptive processes

As discussed above, values of ΔH are traditionally reported for O<sub>2</sub>-selective adsorbents, but the ΔG of O<sub>2</sub> binding is a more meaningful metric for evaluating the performance of a material

under practical working conditions. In particular, the  $\Delta G$  of  $O_2$  binding is a key parameter for determining the useable surface coverage,  $\Delta\theta$ , defined as the difference between the surface coverage under adsorption ( $\theta_{\text{ads}}$ ) and desorption ( $\theta_{\text{des}}$ ) conditions (see ESI Section S6†).<sup>98</sup> The maximal value of  $\Delta\theta$  under a given set of working conditions is 1, corresponding to complete coverage of the primary  $O_2$  binding sites upon adsorption ( $\theta_{\text{ads}} = 1$ ) and zero coverage upon desorption ( $\theta_{\text{des}} = 0$ ). Thus, for a given set of target conditions, it is possible to calculate an optimal  $\Delta G$  value that will maximize theoretical useable capacity. Note that this analysis is intended as a useful starting point, and a comprehensive evaluation of a candidate material will necessarily consider other factors such as  $O_2/N_2$  selectivity (see Section 3.6) and adsorption kinetics.

The specific working conditions for an adsorptive air separation process depend on a multitude of factors, including capital and operating costs, production scale, location, and load variability.<sup>12,18,94,140,141</sup> For the purposes of the present assessment, we considered a VSA process under two sets of working conditions, namely adsorption of air at 1 bar and 298 K and desorption at 10 or 1 mbar, which are common minimum pressures for dry reciprocating pumps. Based on progress achieved thus far in the development of  $O_2$ -selective MOFs and the inherent tunability of these materials, we propose that these conditions represent reasonable targets and additionally would afford considerable costs and energy savings relative to current technologies.

Optimal surface coverage under these two sets of conditions is achieved for  $\Delta G_{298}$  values of  $-10.49$  and  $-7.64$   $\text{kJ mol}^{-1}$ , for desorption at 1 and 10 mbar, respectively. These values are shown as blue and purple lines, respectively, in the plot of  $\Delta S$  vs.  $\Delta H$  given in Fig. 4a. The points plotted in Fig. 4a represent the calculated values of  $\Delta G$  at 298 K associated with  $O_2$  binding at the open metal sites in eight reported frameworks and the hypothetical material *Co-BTP*, based on calculated  $\Delta S$  and  $\Delta H$

values (see the ESI Section S5 for details and Table S11†). An implicit assumption in comparing these data is that the  $\Delta H$  and  $\Delta S$  values for each framework are temperature-independent, given the range of temperatures (typically well below 298 K) used to collect adsorption data. While this assumption is not always valid, as discussed previously for Fe- and Co-PCN-224, these results are intended to serve as a proof-of-concept demonstration of using  $\Delta G$  as a key parameter for more comprehensive benchmarking than has been accessible based on  $\Delta H$  alone. Overall, the data in Fig. 4a highlight that  $O_2$  binding in most of the MOFs analyzed is not sufficiently exergonic for achieving optimal useable surface coverage under the considered conditions. The one outlier is *Cu<sup>I</sup>-MFU-4l*, for which the  $\Delta G$  of  $O_2$  binding at the open copper(i) sites is calculated to be  $-6(1)$   $\text{kJ mol}^{-1}$ . The hypothetical material *Co-BTP* is also predicted to have a near-optimal  $\Delta G$  of  $-11$   $\text{kJ mol}^{-1}$ . Interestingly, recall the  $\Delta G_{298}$  of  $O_2$  binding in the molecule *Fe(T-pivPP)(1-MeIm)<sub>2</sub>* is  $-10.8$   $\text{kJ mol}^{-1}$  (Table 3), which suggests that the pursuit of new framework types featuring analogous iron-porphyrin units may be a promising design strategy. Ultimately, using these values as a guideline for evaluating materials must be done with caution, considering that an optimal  $\Delta G_{298}$  value must be associated with a sufficiently high enthalpy of adsorption to ensure selectivity over  $N_2$  while minimizing regeneration energy.

We also determined  $\Delta\theta$  as a function of  $\Delta G$  for several desorption pressures ranging from 1 to 50 mbar, as shown in Fig. 4b, where the same frameworks from Fig. 4a are indicated as numbered grey lines. As a result of the non-linear dependence of  $\Delta\theta$  on  $\Delta G$  and the desorption pressure (see ESI Section S6†), minor deviations in  $\Delta G$  and  $P_{\text{des}}$  can dramatically impact  $\Delta\theta$ . For example, the lowest desorption pressures are associated with the largest gains in surface coverage. Only *Cu<sup>I</sup>-MFU-4l* and *Co-BTP* exhibit  $\Delta G$  values that give rise to optimal useable surface coverage. Targeting materials that exhibit similar open

Fig. 4 (a) Calculated enthalpy and entropy values of  $O_2$  binding in nine selected frameworks as discussed in the text (colored circles). The optimal Gibbs free energies ( $\Delta G_{\text{opt}}$ ) that maximize  $O_2$  useable surface coverage ( $\Delta\theta$ ) at 298 K for a VSA process with adsorption at 0.21 bar and desorption 1 and 10 mbar are plotted as blue and purple lines, respectively (see Section S6 of the ESI†). (b)  $O_2$  useable surface coverage at 298 K plotted as a function of  $\Delta G$  for a range of desorption pressures, following adsorption at 0.21 bar. The optimal Gibbs free energy ( $\Delta G_{\text{opt}}$ ) associated with the maximum useable capacity at each pressure is also given. The Gibbs free energies of  $O_2$  binding for the same frameworks in (a) are shown in the plot as grey bars. As a result of the non-linear relationship between  $\Delta\theta$  and  $\Delta G$ , minor deviations from  $\Delta G_{\text{opt}}$  have a significant impact on the value of  $\Delta\theta$ . See Tables S13 and S14† for the calculated working capacity of each framework under the considered VSA process conditions.

metal sites and associated enthalpy and entropy values is a worthwhile pursuit.

The combined use of high temperature and vacuum to regenerate an adsorbent, in a so-called vacuum temperature swing adsorption (VTSA) process, can give rise to higher useable surface coverages than accessible with the use of VSA or TSA alone.<sup>14</sup> Additionally, incorporating a temperature swing for desorption enables the recovery of waste heat, albeit generally at the expense of slower cycle times. We assessed the performance of the same MOFs considered above in a VTSA process involving adsorption of air at 298 K and 1 bar (0.21 mbar O<sub>2</sub>) and desorption at 338 K and 10 mbar (Table 5). Under these conditions, *Co-BTP* and Cu<sup>I</sup>-MFU-4l again exhibit the highest useable surface coverages of all the frameworks, with  $\Delta\theta = 0.86$  and 0.71, respectively. These values are comparable to that achieved using a VSA process and desorption at 1 mbar and 298 K. In other words, the  $\Delta 40$  K temperature swing compensates for the 10-fold weaker vacuum in this process. Finally, we emphasize that the foregoing analysis is helpful only to compare the  $\Delta G$  of adsorption across different frameworks and relative to a defined process condition, and this parameter alone is not sufficient to qualify benchmark adsorbents. It is also critical to consider other factors, such as the density of binding sites in an adsorbent, as well as its O<sub>2</sub>/N<sub>2</sub> selectivity (as discussed below).

### 3.6 O<sub>2</sub> working capacities and selectivities

**3.6.1 Working capacities.** The theoretical O<sub>2</sub> capacity of an adsorbent, as determined from the density of open metal sites in the MOFs discussed here, is a property inherent to the material. In contrast, the actual working capacity of the framework will also depend on the process conditions. In general, the greater the working capacity of the material, the lower the operating and capital costs of the adsorptive process. Specifically, increasing gravimetric working capacity (units of mmol g<sup>-1</sup>, for example) can increase the product throughput, defined as kg of O<sub>2</sub> separated per kg adsorbent per hour,

whereas increasing volumetric working capacity (units of g L<sup>-1</sup>, for example) can decrease the necessary contactor size—or the size of the system that contains the adsorbent bed—and therefore capital costs.<sup>12</sup>

To estimate the working capacities of the nine investigated frameworks under the aforementioned VTSA process conditions—O<sub>2</sub> adsorption at 298 K and 0.21 bar/desorption at 10 mbar and 338 K—we first determined an estimated gravimetric O<sub>2</sub> capacity in each case (in units of mmol g<sup>-1</sup>), based on the inflection point in the plot of enthalpy of adsorption as a function of loading (see the ESI Section S5 for details and Table S12†). The gravimetric working capacity in each case was then calculated as the product of this estimated capacity and the process-specific  $\Delta\theta$  value for each MOF. Separately, volumetric working capacities (in units of g L<sup>-1</sup>) were calculated as the analogous product of  $\Delta\theta$  and the estimated volumetric capacity in each case. Each estimated volumetric capacity was obtained as the product of the theoretical volumetric capacity (calculated from the single-crystal density) and the multiplicative factor [estimated capacity (mmol g<sup>-1</sup>)]/[theoretical capacity (mmol g<sup>-1</sup>)] (see Table S12† for details; note that the volumetric density of a pellet might differ substantially from the single-crystal value). Table 5 summarizes the resulting gravimetric and volumetric working capacities for each framework in the VTSA process. The materials Cu<sup>I</sup>-MFU-4l and Co-BDTriP exhibit the highest working capacities of the eight reported frameworks considered, although these capacities are relatively low ( $\sim 1$  mmol g<sup>-1</sup>). Interestingly, the gravimetric working capacity of *Co-BTP* is predicted to be 2.4 mmol g<sup>-1</sup>. Under the VSA process conditions described earlier, Cu<sup>I</sup>-MFU-4l and Co-BDTriP again exhibit the highest volumetric and gravimetric working capacities of the reported materials (see Fig. S2 and Tables S13, S14†). It is noteworthy that the useable surface coverage and gravimetric and volumetric working capacities of those two frameworks are largest even though their associated enthalpies of O<sub>2</sub> binding are not the highest of the materials considered. Ultimately, these data emphasize the importance of

**Table 5** Calculated useable surface coverages ( $\Delta\theta$ ) and gravimetric and volumetric O<sub>2</sub> working capacities for nine frameworks discussed in the text as implemented in VTSA process with  $P_{\text{ads}} = 0.21$  bar O<sub>2</sub> at 298 K and  $P_{\text{des}} = 0.01$  bar at 338 K. Gravimetric working capacities (mmol g<sup>-1</sup>) were obtained by multiplying  $\Delta\theta$  by estimated gravimetric O<sub>2</sub> capacities for each MOF, determined in most cases from the inflection point of the experimental isosteric heat of adsorption as a function of loading (see Section S5 of the ESI for details).<sup>a</sup> Volumetric working capacities (g L<sup>-1</sup>) were calculated by multiplying  $\Delta\theta$  by the estimated volumetric O<sub>2</sub> capacity for each framework (see Table S12 for details)

MOF	Surface coverage, $\Delta\theta$	Working capacity (mmol g <sup>-1</sup> )	Working capacity (g L <sup>-1</sup> )
<i>Co-BTP</i>	0.86	2.4	78.0
Cu <sup>I</sup> -MFU-4l	0.71	1.1	20.3
Co-BDTriP	0.43	0.90	29.2
Mn-PCN-224	0.52	0.29	4.3
Co-BTTri	0.083	0.23	6.8
Fe-BTTri	0.095	0.22	6.2
Fe-PCN-224 HT	0.088	0.048	0.77
Co-PCN-224	0.068	0.048	0.75
Co <sub>2</sub> (OH) <sub>2</sub> (bbta)	0.014	0.035	1.2
Fe-PCN-224 LT	0.039	0.021	0.34

<sup>a</sup> The inflection point was approximated from the second derivative of the enthalpy *versus* loading, estimated using the finite difference method.

considering both  $\Delta H$  and  $\Delta S$  when evaluating potential material targets.

We selected Cu<sup>I</sup>-MFU-4l, Co-BDTrIP, and Co-BTP to further investigate the effects of desorption temperature on volumetric working capacities and useable surface coverages in a VTSA process involving adsorption of air at 298 K and 1 bar (0.21 bar O<sub>2</sub>) and desorption at 0.2 bar (see Fig. S3 and S4,† respectively). The working capacities of Cu<sup>I</sup>-MFU-4l and Co-BDTrIP increase with increasing desorption temperature until they begin to plateau above 370 K, reaching values of ~21 and 29 g L<sup>-1</sup>, respectively, at 418 K. In the case of Co-BTP, the working capacity is projected to increase with temperature up to at least 418 K, the highest temperature considered. As might be expected, the useable surface coverage of each material also generally increases with increasing desorption temperature (Fig. S4†). Interestingly, at the lowest desorption temperatures, Cu<sup>I</sup>-MFU-4l and Co-BDTrIP exhibit slightly higher working capacities and useable surface coverages than Co-BTP, whereas Co-BTP outperforms both frameworks at the highest desorption temperatures.

**3.6.2 O<sub>2</sub>/N<sub>2</sub> selectivities.** The rigorous determination of adsorbent selectivity for one component of a complex mixture, such as O<sub>2</sub> from air, requires the collection of multi-component adsorption data. One approach is to conduct breakthrough experiments, which require a large amount of sample and dedicated instrumentation. However, reasonable selectivity estimates can be obtained using single-component adsorption data and Ideal Adsorbed Solution Theory (IAST).<sup>142</sup> This theory extends Raoult's Law to the adsorbed-gaseous equilibrium and assumes that the adsorbed phase will behave like an ideal solution; IAST has been shown to be accurate across a wide range of adsorbents and gas mixtures.<sup>143,144</sup> However, it is important to note that a redox-mediated adsorption mechanism may result in a non-negligible thermodynamic change in the adsorbent, in which case the assumptions of IAST may not fully hold. In these cases, more accurate assessments of adsorption selectivity can be gained from Monte Carlo simulations.<sup>145–147</sup> Experimentally, adsorption selectivities can also be measured using *in situ* Fourier transform IR<sup>148</sup> and NMR<sup>149</sup> spectroscopies, mass spectrometry coupled with volumetric assays,<sup>150</sup> and multi-component equilibrium adsorption measurements.<sup>151</sup>

Table 4 includes the reported O<sub>2</sub>/N<sub>2</sub> IAST selectivities for several frameworks for a 21 : 79 O<sub>2</sub>/N<sub>2</sub> mixture at 1 bar. Because these values are reported at different temperatures, it is difficult to draw precise comparisons. Nonetheless, we note some key takeaways. For instance, the selectivity of Co-BDTrIP is more than double that of Co-BTTrIP at 195 K, highlighting the power of ligand modifications to tune adsorption properties. However, the most practical materials will be those that are highly selective for O<sub>2</sub> at ambient temperature or above.<sup>14,152</sup> Cr-BTT displays the highest 298 K IAST selectivity of all the materials examined, although it is not entirely stable to repeated cycling.<sup>123</sup> Calculated 298 K IAST values for Cu<sup>I</sup>-MFU-4l and Co-BDTrIP, which exhibit the highest calculated capacities at 298 K, are 6.5 and 14, respectively, for a 21 : 79 O<sub>2</sub>/N<sub>2</sub> mixture at 1 bar (Fig. S5 and S6†). Note that these values are based on isotherm data collected at lower temperatures (203 to 233 K), and it will

be important to validate these estimates experimentally. Even still, based on all the metrics evaluated above, these two MOFs clearly stand apart from the rest as the most promising O<sub>2</sub>-selective adsorbents, and it may be worthwhile to pursue synthetic variants that exhibit further optimized O<sub>2</sub> adsorption properties suitable for practical applications.

### 3.7 O<sub>2</sub> adsorption without metal coordination

We conclude Section 3 with a brief overview of some additional frameworks that have been shown to selectively bind O<sub>2</sub> *via* mechanisms that do not involve redox-active open metal sites. As only a small fraction of frameworks studied to date feature such sites, it is of interest to explore alternative strategies for achieving selective O<sub>2</sub> uptake in metal-organic frameworks.

**3.7.1 Outer-sphere electron transfer.** Recently it was shown that reduced frameworks of the type A<sub>x</sub>Fe<sub>2</sub>(bdp)<sub>3</sub> (A = Na<sup>+</sup>, K<sup>+</sup>; bdp<sup>2-</sup> = 1,4-benzenedipyrazolate; 0 < x ≤ 2)<sup>153</sup> are capable of selectively binding O<sub>2</sub> over N<sub>2</sub> at ambient (25 °C) or even elevated (200 °C) temperatures.<sup>152</sup> These mixed-valence materials are prepared *via* chemical reduction of the parent Fe<sub>2</sub>(bdp)<sub>3</sub> with alkali naphthalenides and feature one-dimensional pyrazolate-bridged chains of coordinatively-saturated iron centers. Notably, O<sub>2</sub> uptake in these materials occurs due to *outer-sphere* electron transfer, in contrast to the MOFs discussed above, and the resulting superoxide moieties are stabilized by alkali cations residing within the pores. A suite of structural and spectroscopic data indicate that superoxide formation is associated with significant rearrangement of the alkali cation positions. This phenomenon is kinetically limiting at ambient temperature, precluding the use of these materials for practical applications. However, the use of larger, templating cations that would promote O<sub>2</sub> reduction may be a means of enhancing cyclability. Ultimately, these results represent an important proof-of-concept of the utility of outer-sphere electron transfer for promoting strong, selective O<sub>2</sub> binding and motivate further pursuit of chemically or electrochemically reduced frameworks for selective O<sub>2</sub> binding.

**3.7.2 O<sub>2</sub> binding at redox-active linkers.** Metal-organic frameworks can also be synthesized with redox-active organic linkers. If these linkers are sufficiently reducing and not sterically encumbered, they may also serve as O<sub>2</sub> binding sites. Few examples of reversible O<sub>2</sub> binding to organic molecules exist,<sup>154,155</sup> and to our knowledge only one example exists in a framework. In particular, the flexible, porous coordination solid comprised of Zn-4,4'-bipyridyl chains bridged by TCNQ (7,7,8,8-tetracyano-*p*-quinodimethane) dimers was shown to bind O<sub>2</sub> at 77 K.<sup>156</sup> Although the adsorption data were obtained below the boiling point of O<sub>2</sub> and are therefore not directly relevant to the separation of O<sub>2</sub> from air, these results are nonetheless intriguing. Indeed, *in situ* IR and Raman spectroscopy data suggest partial charge transfer from the TCNQ dimers to O<sub>2</sub>. It may be possible to access more reduced O<sub>2</sub> species in MOFs, and at higher temperatures, through the use of more reducing linkers. For example, electrochemically reduced trinitroarene molecules have been shown to reversibly bind O<sub>2</sub> as μ-O<sub>2</sub><sup>2-</sup> species.<sup>154,155</sup>

**3.7.3 Additional binding modalities.** A small number of materials have been reported to selectively bind O<sub>2</sub> over N<sub>2</sub> through other diverse mechanisms. We highlight a few examples here, although in most cases the selectivity for O<sub>2</sub> is not fully explained. The framework Sc<sub>3</sub>(btc)<sub>2</sub> exhibits slight selectivity for O<sub>2</sub> over N<sub>2</sub> at 298 K, which was attributed to framework flexibility and a purported favorable binding pocket for O<sub>2</sub>.<sup>157</sup> The microporous metal formate Mn(HCOO)<sub>2</sub> has also been shown to selectively adsorb O<sub>2</sub> over Ar and N<sub>2</sub> below 140 K, although the mechanism is not well-understood.<sup>158</sup> Finally, a family of multicomponent frameworks featuring triangular Cu<sup>I</sup><sub>3</sub>(HPyC)<sub>3</sub> (HPyC<sup>−</sup> = 4-pyrazolecarboxylate) units have been shown to undergo facile oxidation in the presence of water.<sup>159</sup> Upon oxidation, the linear copper(I) centers are converted to square planar copper(II) with coordination spheres completed by a terminal hydroxide and μ<sup>3</sup>-OH. This reaction is reversible with heating under vacuum or treatment with a mildly reducing solvent. This mechanism is clearly distinct from the other modes of O<sub>2</sub> binding at transition metal sites discussed above, and it is interesting to consider, as a more general strategy, the use of water or other small molecules to facilitate reversible O<sub>2</sub> adsorption in MOFs.

## 4. Density functional theory calculations of O<sub>2</sub> binding in MOFs

### 4.1 DFT-based methods for predicting O<sub>2</sub> binding energies in MOFs

Density functional theory-based computational studies of O<sub>2</sub> binding in MOFs can play an important role in supporting experimental design and characterization efforts, and in advancing understanding of binding mechanisms. In general, it can be a challenge to predict the nature of small molecule binding at coordinatively-unsaturated, open-shell transition metals in MOFs using contemporary DFT methods, given that unit cells may contain hundreds of atoms, and because standard functionals can fail to adequately treat exchange and correlation effects associated with van der Waals dispersion and states having open-shell spin and localized d orbital character. Previous studies that have predicted energies associated with O<sub>2</sub> binding to open metal sites in MOFs have used DFT calculations that either treat the full crystalline system with periodic boundary conditions<sup>160–162</sup> or focus on the local O<sub>2</sub> binding environment using cluster models.<sup>44,163,164</sup>

MOFs are highly ordered, crystalline materials that can be modeled using periodic boundary conditions, and periodic DFT calculations, typically carried out using an entire unit cell, can enable a realistic description of the framework structure. Important onsite correlation effects—associated with redox-active transition metal centers with open d shells—can be addressed with periodic DFT calculations using hybrid functionals or semi-empirical Hubbard *U* corrections (so-called “DFT + *U* calculations”),<sup>161</sup> which act on the d-states localized on the metal centers. Although empirical in nature and approximate, Hubbard *U* corrections can lead to improved treatments of electron–electron interactions and are less computationally

expensive than using hybrid functionals on a MOF with a large unit cell. It should be noted that prior calculations of energies associated with O<sub>2</sub> (ref. 160 and 161) and CO<sub>2</sub> (ref. 40 and 165) binding in MOFs using DFT + *U* have shown that the energies can increase or decrease monotonically with increasing *U*, depending on the nature of binding. While it is possible to obtain Hubbard *U* values with a first-principles approach, such values do not always improve agreement with experiment.<sup>158,162</sup>

Cluster calculations, where only a small number of atoms near the binding site are treated explicitly, can reduce computational complexity while allowing for a more accurate treatment of open-shell systems, through more efficient use of hybrid functionals or more rigorous treatment of local interactions, for example through the use of so-called higher-rung density functionals or even beyond-DFT wave-function based quantum chemistry approaches. However, care must be taken when choosing this approach, as cluster calculations do not consider long-range interactions, which may be important in influencing experimental O<sub>2</sub> binding properties. Relatedly, cluster calculations typically “lock in” the positions of certain atoms, fixing them to their periodic bulk positions, to prevent atomic displacements that would be unfeasible or unrealistic in the extended MOF system. If the initial constrained bond lengths are unfeasibly large (or small) based on the experimentally known spin state for an O<sub>2</sub>-bound metal site, it can be difficult to converge the calculation to the correct spin state. Knowledge of the metal–ligand bond lengths alone leaves some ambiguity for how one ought to fix the atomic positions in the cluster. This ambiguity is less of an issue when performing calculations with periodic boundary conditions, where the atomic positions and lattice parameters can relax with greater freedom. For scenarios where calculations on truncated MOF clusters are desirable due to the aforementioned advantages, a periodic DFT calculation at a lower level of theory can first be performed to establish reasonable bounds for variations in bond lengths.<sup>44</sup>

### 4.2 DFT calculations of O<sub>2</sub> binding in M-benzenetrisazolates

In this section, we describe the results of DFT calculations performed using clusters and periodic boundary conditions to determine predicted O<sub>2</sub> binding energies in the M-BTT, M-BTTri, and hypothetical *M-BTP* frameworks (M = Cr<sup>II</sup>, Mn<sup>II</sup>, Fe<sup>II</sup>, Co<sup>II</sup>). The M-benzenetrisazolates were chosen for this purpose as they represent the largest and most thoroughly investigated family of materials studied to date for O<sub>2</sub> capture and exhibit promising capacities, adsorption enthalpies, and metal site densities.

For DFT cluster calculations, we used the four-metal cluster [M<sub>4</sub>Cl(azolate)<sub>8</sub>]<sup>−</sup> to represent the local binding site and the TPSSH hybrid functional (see Fig. S7 and ESI Section S7.2† for details). As shown in Fig. 5a, our DFT calculations predict an increase in the O<sub>2</sub> binding strength with increasing basicity of the azolate linker for all four metals considered, consistent with available experimental data. The calculated O<sub>2</sub> binding energies for the model clusters for Fe-BTTri, and Co-BTTri are larger than

**Fig. 5** (a) Results of DFT cluster calculations for O<sub>2</sub> binding energies in a series of model four-metal clusters  $[M_4Cl(\text{azolate})_8]^-$  ( $M = \text{Cr}^{\text{II}}, \text{Mn}^{\text{II}}, \text{Fe}^{\text{II}},$  and  $\text{Co}^{\text{II}}$ ; azolate = pyrazolate, triazolate, or tetrazolate to represent  $\text{BTP}^{3-}, \text{BTTri}^{3-},$  or  $\text{BTT}^{3-}$  linkers). The TPSSh functional was used for  $M = \text{Mn}^{\text{II}}, \text{Fe}^{\text{II}},$  and  $\text{Co}^{\text{II}}$ , and M06 was used for  $\text{Cr}^{\text{II}}$  (see Section S7.2 of the ESI† for details). Experimental enthalpy values are shown as black circles for Cr-BTT, Fe-BTTri, and Co-BTTri. As can be seen, TPSSh tends to overestimate experimental binding energies. Binding energies trend with the basicity of the azolate across all metals. (b) DFT calculations with periodic boundary conditions (PBE-D3 +  $U$ ,  $U = 3.3$  eV) for O<sub>2</sub> binding energies for the series of  $[(\text{Co}_4\text{X})_3(\text{benzenetrisazolate})_8]$  ( $\text{X} = \text{F}^-, \text{Cl}^-, \text{Br}^-,$  and  $\text{I}^-$ ; benzenetrisazolate =  $\text{BTT}^{3-}, \text{BTTri}^{3-},$  and  $\text{BTP}^{3-}$ ). The experimental O<sub>2</sub> binding enthalpy for Co-BTTri is shown as a black circle. Notably, binding energies trend with the electropositivity of the halide.

the experimentally determined enthalpies for the frameworks, but we note that the degree of over- or under-estimation is heavily influenced by the choice of exchange-correlation functional (see Table S18†). Overall, our calculations suggest that Mn-BTP, Fe-BTT,<sup>125</sup> and Co-BTP may be promising materials for O<sub>2</sub> separations, given that their predicted binding energies are near the proposed optimal binding enthalpy of  $-45 \text{ kJ mol}^{-1}$  (refer to Section 3.1). We note that while the synthesis of Co-BTT has been reported,<sup>127</sup> its O<sub>2</sub> adsorption properties have not been investigated. Based on these calculations and the experimental enthalpies of O<sub>2</sub> adsorption in the congeners with more basic ligands (Co-BTTri and Co-BTTriP), Co-BTT is not likely of interest for further study related to air separations.

Our calculations of O<sub>2</sub> binding to open metal sites in the M-benzenetrisazolate frameworks were carried out using periodic

boundary conditions with an eye toward identifying other isostructural materials that may display O<sub>2</sub> binding enthalpies near the proposed optimal value of  $-45 \text{ kJ mol}^{-1}$ . We started with the experimentally determined structure for Co-BTTri and replaced the linker or halide to obtain the various structures considered. Calculations were performed on unit cells of the type  $[(\text{Co}_4\text{X})_3(\text{benzenetrisazolate})_8]$  ( $\text{X} = \text{F}^-, \text{Cl}^-, \text{Br}^-,$  and  $\text{I}^-$ ; benzenetrisazolate =  $\text{BTT}^{3-}, \text{BTTri}^{3-},$  and  $\text{BTP}^{3-}$ ) without charge balancing cations. As such, to represent the anionic framework accurately with an overall neutral unit cell, we added three extra electrons and a positive neutralizing background charge (see ESI Section S7.1† for details). All of the atoms and the lattice vectors were then relaxed. We performed all DFT calculations with PBE +  $U$ , and we also employed a pairwise correction term, Grimme D3, to capture van der Waals dispersion corrections. These periodic DFT + D3 +  $U$  calculations ultimately enabled us to perform full geometry optimizations without constraining the positions of the atoms, as is necessary in the cluster calculations.

As shown in Fig. 5b, these calculations predict that the O<sub>2</sub> binding energy increases upon moving from  $\text{X} = \text{F}^-$  to  $\text{I}^-$ . This result may be explained by considering that the electron density around the cobalt sites will increase with the electropositivity of the  $\mu^4$ -halide, and therefore charge transfer to O<sub>2</sub> would be increasingly favored. The results further suggest that  $\text{Co}_3[(\text{Co}_4\text{Br})_3(\text{BTTri})_8]_2$ ,  $\text{Co}_3[(\text{Co}_4\text{I})_3(\text{BTTri})_8]_2$ ,  $\text{Co}_3[(\text{Co}_4\text{F})_3(\text{BTP})_8]_2$ , and  $\text{Co}_3[(\text{Co}_4\text{Cl})_3(\text{BTP})_8]_2$  may be promising target materials. While the absolute binding energies will be dependent upon the choice of exchange–correlation functional, including the choice of the method used to treat dispersion interactions and the Hubbard  $U$  value chosen, it is expected that trends found with a given functional should hold for other choices of functional. Thus, since  $\text{Co}_3[(\text{Co}_4\text{Cl})_3(\text{BTTri})_8]_2$  has an experimental binding energy below the target value of  $-45 \text{ kJ mol}^{-1}$ , based on our calculated trends, we would expect that  $\text{Co}_3[(\text{Co}_4\text{X})_3(\text{BTTri})_8]_2$  with  $\text{X} = \text{Br}$  or  $\text{I}$  would have binding enthalpies close to  $-45 \text{ kJ mol}^{-1}$ . Since no members of the  $\text{Co}_3[(\text{Co}_4\text{X})_3(\text{BTP})_8]_2$  series have yet been synthesized, whether any of its variants would have a binding enthalpy near  $-45 \text{ kJ mol}^{-1}$  is unclear, although we would expect from our trends that  $\text{Co}_3[(\text{Co}_4\text{Cl})_3(\text{BTP})_8]_2$  would bind O<sub>2</sub> more strongly than  $\text{Co}_3[(\text{Co}_4\text{Cl})_3(\text{BTTri})_8]_2$  and that substituting chloride with larger halides would increase the binding enthalpy.

### 4.3 Benchmarking entropic contributions to O<sub>2</sub> binding in MOFs

While the calculation of O<sub>2</sub> binding enthalpies is important for evaluating candidate adsorbents, the free energy of adsorption enables a more holistic evaluation of material performance, as discussed in detail above. Obtaining vibrational properties from calculations allows one to additionally calculate  $\Delta S$  and estimate the  $\Delta G$  of adsorption. With the calculated free energy in hand, one can also estimate the adsorption isotherm from an *ab initio* calculation. In addition, vibrational calculations provide the O–O stretching frequency, an important observable for determining the degree of charge transfer to dioxygen.

Given the predominant focus in the experimental literature on the enthalpy of O<sub>2</sub> binding in candidate MOFs, computational efforts have also often focused on this thermodynamic variable. To support future computational and experimental efforts in this area, we investigated how accurately cluster calculations can estimate the  $\Delta S$  of O<sub>2</sub> binding for the systems of interest here. We chose the M-PCN-224 (M = Mn<sup>II</sup>, Fe<sup>II</sup>, Co<sup>II</sup>) family as a model system because (i) their experimental O<sub>2</sub> binding entropies span a wide range of values (see Fig. 4a) and (ii) the cubic pore shape, face-centered location of the porphyrins (see Fig. 3f), and pore size (approximately 19 Å) are such that one may less ambiguously select the relevant cluster—in this case the metal–porphyrin molecule—when compared to the M-BT<sup>Tri</sup> series.

We first examined various functionals for their accuracy in predicting binding energy. In the case of Mn-porphyrin, many commonly used functionals, even ones benchmarked to transition metal datasets (e.g., MN15,  $\omega$ B97X-D, M06, PBE0),<sup>166–169</sup> failed to predict the peroxide species bound to Mn(II) (see ESI Section S7.3 for details and Table S20†). Both TPSSh and B97M-rV yielded good estimates of binding energies, but B97M-rV requires far more expensive frequency calculations. Ultimately, TPSSh correctly identified the peroxide and superoxide species that form upon O<sub>2</sub> binding in Mn- and Fe-porphyrin, respectively. The calculated entropy of O<sub>2</sub> binding in Mn-porphyrin is very close to the value calculated for Mn-PCN-224 using the Clausius–Clapeyron relationship ( $-179$  vs.  $-174 \pm 20$  J mol<sup>-1</sup> K<sup>-1</sup>, respectively, see Tables S20 and S11†). Similarly, the calculated entropy of O<sub>2</sub> binding in Fe-porphyrin is  $-143$  J mol<sup>-1</sup> K<sup>-1</sup>, consistent with the value of  $-121 \pm 30$  J mol<sup>-1</sup> K<sup>-1</sup> determined for Fe-PCN-224 at low temperature (Tables S21 and S11†). In contrast, TPSSh did not identify the superoxide species bound in Co-porphyrin, and the calculated O<sub>2</sub> binding entropy is much larger than that determined for Co-PCN-224 ( $-139$  vs.  $-59.6 \pm 0.7$  J mol<sup>-1</sup> K<sup>-1</sup>, respectively).

## 5. Conclusions and outlook

As a result of their high surface areas and atom-level tunability, metal–organic frameworks have emerged as promising candidates for O<sub>2</sub>-selective adsorptive air separations. In particular, a number of MOFs featuring coordinatively-unsaturated redox-active metal sites have been discovered to date that are capable of selectively binding O<sub>2</sub> over N<sub>2</sub>. Additional strategies for selective O<sub>2</sub> adsorption have also begun to emerge, such as outer-sphere electron transfer from redox-active frameworks and non-redox-mediated chemisorption of O<sub>2</sub>. Overall, the continued investigation of new MOFs and O<sub>2</sub> adsorption mechanisms is a key fundamental driver of this important, nascent area of research.

With an eye toward practical applications, frameworks with open metal sites are the most promising materials studied to date. Design strategies have focused on tuning the linker and local coordination environment to generate open metal sites that are sufficiently reducing for selective O<sub>2</sub> binding and can be regenerated using relatively mild swings in temperature or pressure. However, significant improvements are still needed to

render MOFs competitive with the incumbent adsorptive air separation technology based on nitrogen-selective zeolites.

Drawing on inspiration from molecular and biological systems that strongly and reversibly bind O<sub>2</sub>, we have identified design considerations for further enhancing selective, reversible O<sub>2</sub> uptake in MOFs (Section 2), surveyed key frameworks studied to date for selective O<sub>2</sub> uptake (Sections 3.2–3.4), and evaluated relevant performance metrics (Sections 3.5 and 3.6). While the enthalpy of O<sub>2</sub> binding has traditionally been used to judge material performance, it is the free energy of adsorption,  $\Delta G$ , that is most important in evaluating suitability for a practical separation process. Thus, going forward, it will be critical for researchers to adopt a more holistic approach, considering both the enthalpy and entropy of O<sub>2</sub> binding in the evaluation of any new MOF for air separations. Other important parameters to consider are gravimetric and volumetric O<sub>2</sub> capacities, based on exposed metal site density, which can readily be estimated from experimental data.

For new frameworks, it will be critical to characterize these properties under working conditions relevant for practical separations, and ambient temperature data should be reported when possible. More rigorous characterization will in turn enable a greater fundamental understanding of O<sub>2</sub> binding at open metal sites. Never has it been so facile to determine thermodynamic parameters for O<sub>2</sub> binding across isostructural series, as exemplified in the case of the M-PCN-224 (M = Mn<sup>II</sup>, Fe<sup>II</sup>, Co<sup>II</sup>) frameworks. Importantly, this understanding will also carry over to other fields working on O<sub>2</sub> activation and reactivity.<sup>170</sup>

The free energy of O<sub>2</sub> binding can ultimately be used to determine optimal working conditions for a given adsorbent, or alternatively, to identify an optimal adsorbent for a given set of working conditions. Using available experimental data, we put the latter concept into practice and evaluated the performance of nine MOFs in representative vacuum swing and vacuum/temperature swing adsorption processes. Two known MOFs, Cu<sup>I</sup>-MFU-4l and Co-BD<sup>Tri</sup>P, and the hypothetical material *Co-BTP*, stood out from this analysis as top performers. Beyond this practical insight, these results also suggest that design iterations based on the former two frameworks (and pursuit of *Co-BTP*) are promising research directions.

Finally, it is important to note that the guidelines established here encompass only material-level factors that can be tuned to accelerate the development of O<sub>2</sub>-selective MOFs. Beyond initial design, characterization, and identification of promising candidates, numerous system level factors will also be key to consider in prioritizing materials, such as pellet density, thermal conductivity, cost of synthesis, and impurity resilience. In all, there is a wealth of chemistry yet to be explored in the development of MOFs for selective O<sub>2</sub> capture.

## Author contributions

D. E. J., T. D. H., and J. R. L. conceived the manuscript. D. E. J., A. J., B. E. R. S., A. S., E. T., R. R., M. N. D., W. D., J. B. N., T. D. H., and J. R. L. prepared and contributed to portions of the

manuscript. K. R. M. provided a critical review and contributed to revisions.
