Intrinsic activity modulation and structural design of NiFe alloy catalysts for an efficient oxygen evolution reaction

Qiaoling Kang,^a Dawei Lai,^b Wenyin Tang,^b Qingyi Lu *^a and Feng Gao *^b

NiFe alloy catalysts have received increasing attention due to their low cost, easy availability, and excellent oxygen evolution reaction (OER) catalytic activity. Although it is considered that the co-existence of Ni and Fe is essential for the high catalytic activity, the identification of active sites and the mechanism of OER in NiFe alloy catalysts have been controversial for a long time. This review focuses on the catalytic centers of NiFe alloys and the related mechanism in the alkaline water oxidation process from the perspective of crystal structure/composition modulation and structural design. Briefly, amorphous structures, metastable phases, heteroatom doping and *in situ* formation of oxyhydroxides are encouraged to optimize the chemical configurations of active sites toward intrinsically boosted OER kinetics. Furthermore, the construction of dual-metal single atoms, specific nanostructures, carbon material supports and composite structures are introduced to increase the abundance of active sites and promote mass transportation. Finally, a perspective on the future development of NiFe alloy electrocatalysts is offered. The overall aim of this review is to shed light on the exploration of novel electrocatalysts in the field of energy.

1. Introduction

Given the limited fossil energy storage and the environment deterioration caused by fossil fuel consumption, shifting from fuel-based economic development to a sustainable and clean economy is an urgent need but a huge challenge at present.^{1–8} Accordingly, electrochemical water splitting, producing H₂ at the cathode and O₂ at the anode has been widely researched as promising technology to solve the energy crisis.^{9–13} However, due to the sluggish kinetics of the oxygen evolution reaction (OER), especially the huge dynamic barrier resulting from the four-step proton-coupled electron transfer process, effective catalysts are needed to narrow the gap between theoretical calculations and actual required potentials.^{14–20} Although some noble metal-based materials, such as RuO₂ and IrO₂, have been demonstrated to be highly efficient OER electrocatalysts, their high cost and scarcity severely restrict their large-scale commercialization.^{21–25} This serves as a strong driving force to stimulate the investigation of non-noble metal-based OER electrocatalysts.

Among the numerous reported 3d transition metal-based electrocatalysts, NiFe-based materials have been brought to the forefront due to their excellent electrocatalytic performances and low cost.^{26–28} Remarkable achievements have been made regarding the use of transition metal alloys, which exhibit superior performances mainly originating from their inherent electronic and chemical properties.^{29–31} Among them, the NiFe bimetallic alloy is one of the most promising candidates to expedite the kinetically sluggish OER owing to its low cost and intrinsic catalytic activity.^{32,33} In past six years (2015–2020), the number of publications and relevant citations on NiFe alloy electrocatalysts have increased rapidly, as shown in Fig. 1a. Great efforts have been devoted to design alloy nanostructures with a large surface area, well-exposed active sites, and good electronic conductivity to lower the overpotential remarkably for oxygen evolution (Fig. 1b). The recently reported NiFe alloy catalysts exhibit superior catalytic activities, and thus are expected to replace expensive noble metal catalysts.^{34,35} Meanwhile, the progressive insight into the structure–activity relationship has further revealed the properties and mechanism of NiFe alloy catalysts. Following recent achievements, it appears necessary to propose a comprehensive, authoritative, and critical review to emphasize their principles for electronic/structural modulation. In this perspective, we cover the impressive progress in explaining the active roles of NiFe alloy catalysts for OER catalysis together with the optimization of their intrinsic activity (including crystal structure modulation and composition optimization) and structure. Furthermore, we

highlight the crystal/composition/structure–performance relationship of NiFe alloy catalysts. In the case of crystal structure and composition optimization, amorphous structures, metastable phases, heteroatom doping and *in situ* formation of oxyhydroxides are encouraged to optimize the chemical configurations of active sites toward intrinsically boosted OER kinetics. Conversely, for structure optimization, the construction of dual-metal single atoms, specific nanostructures, carbon material supports and composite structures is introduced to increase active-sites and promote electrocatalytic performances. Finally, the challenges and future perspectives will be emphasized for guiding the rational engineering of NiFe alloy electrocatalysts for applications in energy conversion devices.

2. Intrinsic activity optimization

Generally, the optimization of the crystal structure and composition of NiFe alloy electrocatalysts aims at enhancing the intrinsic catalytic efficiencies of their active sites.³⁶ The first significant task is determining the actual active species of NiFe alloys for OER catalysis and the second is to modify their active sites. Designing disordered amorphous phases, metastable phases with high energy, foreign atom in metal alloy systems and *in situ* formation of oxyhydroxides on the NiFe alloy surface usually result in surprising improvements in catalytic activity. The reason for this is that the modification of the electronic or geometric structures leads to a shift in the bonding energy toward the adsorption/desorption of the OER intermediates on the catalyst surface. Hence, initially, we focus the optimization of the intrinsic activity of NiFe alloys toward OER catalysis *via* phase construction (including amorphous and metastable crystal phases), foreign atom doping (including metal atom doping and nonmetallic atom combination) and *in situ* formation of oxyhydroxides for the improvement of their electrochemical performance.

2.1 Crystal structure modulation

2.1.1 Amorphous NiFe alloy. Recently, amorphous materials with unique short-range atomic ordering but long-range disordered structure have attracted increasing attention in electrocatalysis, particularly in water splitting, and exhibit better catalytic activities in terms of overpotential compared with their crystalline counterparts. It has been reported that an amorphous structure can offer more active sites for the OER.^{37–39} Cai *et al.* presented a room-temperature solution technique to prepare an amorphous NiFe alloy catalyst for water oxidation.⁴⁰ The amorphous feature of the as-prepared NiFe alloy catalyst was verified by HAADF-STEM imaging and XRD (Fig. 2a and b), respectively. The amorphous NiFe alloy catalyst could reach a water oxidation current density of 10 mA cm^{-2} at an overpotential of 265 mV, which is 100 mV lower than that of its crystalline counterpart. With comprehensive characterization, it was demonstrated that due to the short-range order of the amorphous structure, the amorphous NiFe alloy catalyst can be electrochemically activated to expose its active sites by applying a positive anodic potential, which can significantly increase the number of active sites, and thus greatly improve the water oxidation activity.

Besides single amorphous NiFe alloy nanoparticles, compounding amorphous NiFe alloys with other materials can further increase the number of active sites. 2D nanomaterials exhibit unique properties and have received wide attention as high performance electrocatalysts. Wang *et al.* presented a self-assembly route on the inert base of 2D materials to construct highly disordered amorphous NiFe/MoS₂ heterostructure materials, which exhibited extraordinary electrocatalytic performances towards the OER in alkaline media (Fig. 2c).⁴¹ The superior OER activity of the highly disordered amorphous NiFe/MoS₂ materials was attributed to two aspects. Firstly, the highly disordered amorphous NiFe alloy could expose a great number of active sites and suppress the aggregation of the active sites,

leading to the comparable OER performances to commercial RuO₂. Secondly, according to the XPS analyses (Fig. 2d and e), the amorphous NiFe alloy showed strong electronic interaction with the support MoS₂, resulting in the beneficial modification of surface electronic structure, which reduced the free energy for adsorption of the intermediates, and thus enhanced the catalytic performances.

In comparison to nanoparticles and 2D materials, 3D amorphous NiFe nanostructured electrodes have also attracted great interest. By combining a 3D nanostructure and amorphous NiFe phase, amorphous NiFe nanotube arrays were fabricated on nickel foam (NiFe NTAs-NF) through electrodeposition and demonstrated to be a high-performance bifunctional electrocatalyst for overall water splitting with low overpotentials of 216 mV for OER at 50 mA cm⁻² and 181 mV for the HER at 10 mA cm⁻² (Fig. 2f-i).⁴² The high catalytic activity of the amorphous NiFe NTAs-NF can be contributed to the synergistic effect resulted from the strong electron interactions between Ni and Fe, which led to the creation of more active sites and more efficient mass and charge transport capability. Also, it can be further contributed to the amorphous nature of the NiFe nanotubes, which increased the density of active sites due to the short-range order, improved the charge-transfer rate by providing easy pathways for charges and made the NiFe nanotubes more durable to the structural tension occurring in water splitting due to their higher structural flexibility than crystalline structures.

Briefly, the short-range order of amorphous materials can increase the density of active sites due to their abundant randomly oriented bonds compared to crystalline structures, and the structural flexibility of amorphous materials can endow greater durability in the water splitting process, leading to enhanced electrocatalytic performances for the OER.⁴³⁻⁴⁵

2.1.2 Metastable crystalline NiFe phase. Generally, metal alloys can crystallize in different crystalline forms, such as face-centered tetragonal (fct), body-centered cubic (bcc), hexagonal close-packed (hcp) and face-centered cubic (fcc) structures.^{46,47} The stacking mode of metal atoms in crystals results in distinct crystal structures and electronic properties, which greatly influence the intrinsic catalytic properties of metal alloys. The familiar fcc-phase NiFe alloy has been reported to be an attractive material for the OER. The simplest method for the synthesis of fcc-phase NiFe alloy is to reduce NiFe-based metallic oxide with reducing agents such as high temperature H₂ or NaBH₄. For example, Lim *et al.* reported the synthesis of NiFe alloy nanoparticles through a facile hydrothermal process and subsequent high temperature reduction under an H₂/Ar atmosphere (Fig. 3a and b).⁴⁸ The synthesized electrocatalyst with an fcc alloy structure exhibited enhanced OER activities with a relatively low overpotential of 298 mV at 10 mA cm⁻². In comparison to single Ni and Fe, alloying Ni with Fe in the fcc phase could improve the conductivity, modify the redox properties of the Ni sites, and generate structural disorder due to the

incorporation of Fe, all of which led to an improvement in OER performance. Additionally, it was demonstrated that the partial oxidation of the surface of the NiFe alloy to NiOOH and FeOOH is also a key factor for the OER enhancement.^{49,50}

Commonly, the synthesized NiFe alloys are typical fcc phase due to its stability. It is difficult to obtain unusual NiFe phases such as the hcp phase, which highlights a new strategy to develop optimized OER catalysts. Wang *et al.* proposed a simple strategy by controlling the annealing temperature to obtain hcp-phase NiFe NPs encapsulated in an N-doped carbon (NC) shell (hcp-NiFe@NC) instead of fcc-NiFe@NC (Fig. 3c–e).⁵¹ The hcp-NiFe@NC catalyst delivered significant OER activity with an unexpectedly low overpotential of 226 mV at 10 mA cm^{-2} , which was 66 mV lower than that of fcc-NiFe@NC in 1.0 M KOH electrolyte (Fig. 3f). The two samples showed almost the same structural characteristics including morphology, size, BET surface area, Raman spectra and N-doping content, and thus their significant difference in OER activity mainly originated in the different phases of NiFe alloy nanoparticles. It was evidenced that the carbon shell encapsulating the NiFe nanoparticles provides direct active sites. Its surface electronic state can be tuned with an increase in the density of states near the Fermi level by the penetration of metal electrons, which can facilitate the catalytic activity. Thus, the modulation of the electronic structure of the NiFe alloy metal core can optimize the OER activity of metal@NC catalysts. In this case, the crystal structure and electronic property of the hcp-phase NiFe alloys are quite different from that of their fcc counterparts. They are more favorable to tailor the external NC electronic state to achieve superior OER activity than fcc-phase NiFe alloys, arising from the unusual intrinsic crystal structure and electronic property.

Briefly, as mentioned above, the stacking mode of the metal atoms in crystals results in distinct crystal structures and

electronic properties, which greatly influence the intrinsic catalytic properties of metal alloys. Thus, crystal phase modulation of NiFe metal alloys provides a potential strategy for the enhancement of their OER activity.

2.2 Heteroatomic doping

2.2.1 Metallic heteroatomic doping.

As is known, water oxidation requires four electrons. Thus, a catalyst containing multiple redox-active metal ions can buffer the multi-electron transfer processes.^{52–56} Nanostructured alloys with multiple redox-active metals may provide new insights into the synergy among different elements and improve the OER catalytic activity. Based on this theory, the addition of a third element to the NiFe alloy would inject more possibilities to regulate its structure and performance.^{57,58} Extensive investigations of *in situ* X-ray absorption spectroscopy (XAS) and voltammetric techniques have revealed that the OER activity of NiFe alloys is strongly dependent on the local environment of Ni and Fe.⁵⁹ Thus, the incorporating transition metals in NiFe alloys can alter the lattice and bond length and then adjust the adsorption energies toward optimal catalytic activities. In addition, it also provides a greater chance to improve the catalytic activity through changing the relative metal proportion in alloys due to the increased degree of freedom of alloys compared with pure metals.⁶⁰ A successful example is the introduction of metal copper in the NiFe alloy to form core-shell nickel-iron-copper (CS-NiFeCu) (Fig. 4a–d).⁶¹ The parent alloy with a dendritic structure was prepared *via* electrodeposition. The introduction of the third element synergistically improved its intrinsic activity and the obtained CS-NiFeCu delivered a very low overpotential of 180 mV at 10 mA cm^{-2} in 1 M KOH alkaline solution (Fig. 4e). The high catalytic performance of CS-NiFeCu for water oxidation was obviously attributed to the synergistic effect of Ni,

Fe and Cu, and the relative amount of copper in the material played a crucial role in enhancing the ECSA and intrinsic catalytic activity. Another example is the core-shell Cr-doped NiFe alloy (CS-NiFeCr) on a 3D Cu nanoarray prepared *via* a simple electrodeposition-activation method (Fig. 4f).⁶² The CV studies were measured for all the CS-NiFe_{0.10}Cr_x samples to investigate the influence of Cr doping on their redox behaviors (Fig. 4g), which confirmed that the incorporated electron-deficient Cr³⁺ can act as a strong Lewis acid to promote the electron delocalization and withdraw the electron density from Ni and Fe. The more electrophilic Ni or Fe sites facilitate the nucleophilic addition of hydroxyls and water molecules on the catalyst surface in the water oxidation process. Thus, the combination of this electronic modulation with nanostructure construction provides a synergistic promotion effect on OER: excellent mass transport by the 3D nanoarchitecture, accelerated charge transfer on the metal/metal hydroxide interface, and improved reaction kinetics by electronic modulation with

the incorporation of Cr, which resulted in excellent OER activity with an overpotential of 200 mV at 10 mA cm⁻².

In addition to monoatomic doping, high entropy alloys (HEAs) containing five or more near-equimolar elements have attracted great interest as catalytic materials in the past several years.^{63–65} In HEAs, the atomic size of each component is different, which can cause lattice distortion, and the presence of multiple components is conducive to promote the formation of the solid solution phase and inhibit the movement of dislocations, both of which are beneficial for an enhancement in electrocatalytic activity. As an example, Huang *et al.* used a one-step solvothermal method to grow a freestanding nanorod-shaped precursor of quinary metal-organic frameworks (*i.e.*, MnFeCoNiCu HEAN MOFs) on the surface of carbon cloth, followed by a high temperature pyrolysis process to form multi-metal high entropy MnFeCoNiCu alloys (Fig. 4h and i).⁶⁶ The high-entropy MnFeCoNiCu alloys contained highly deformed lattices and various defects, such as dislocations, twins and stacking faults, which led to high surface tension and

substantial reduction of the overpotential for the OER to 263 mV at 10 mA cm⁻² with a very low Tafel slope of 43 mV dec⁻¹ (Fig. 4j). The remarkable electroactivity of HEAs in the

OER can be further attributed to the synergistic effect of each element for efficient electron transfer. The suitable electronic environment of HEAs realizes multi-active sites for the

appropriate adsorption of key intermediates and efficient electron transfer during electrocatalysis, which maximize the utilization of surface electroactivity. Thus, high entropy alloys have become a potential platform to discover new alloys with outstanding electrocatalytic activities.

2.2.2 Nonmetallic heteroatomic combination. Nonmetallic heteroatomic combination has been reported as an effective way to adjust the electronic structure and improve the conductivity of NiFe alloy catalysts. When the NiFe alloy is combined with a non-metallic heteroatom (such as P, S or N), the catalytic role is still the center of NiFe, but the presence of the non-metallic heteroatom tunes the electronic structure of Ni and Fe, which is beneficial for accelerating the charge transport process. This results in an increase in the average oxidation state of Ni/Fe in the composites, thereby promoting the water oxidation reaction.⁶⁷ Kang *et al.* combined a sol-gel method and a carbonization-assisted route to facilitate the fabrication of a series of transition metal phosphide nanoparticles (Fig. 5a).⁶⁸ The resultant NiFeP@C exhibited excellent activities as a bifunctional electrocatalyst toward the OER and HER with low overpotentials of 260 and 160 mV, respectively, at 10 mA cm⁻² in 1 M KOH solution. The XPS analysis results showed that the binding energy of Ni 2p shifted positively, while the Fe 2p and the P 2p binding energies showed negative shifts (Fig. 5b-d), suggesting that the electrons around the Ni and Fe environment can be modulated to facilitate electron transport during electrocatalysis when combined with non-metallic elements.

Besides the combination of NiFe with P, Ni *et al.* fabricated (NiFe)S₂ pyrite mesocrystals in the form of nearly single crystalline porous cubes (Fig. 5e and f).⁶⁹ The obtained (NiFe)S₂ pyrite mesocrystals showed a great OER performance with an overpotential of less than 260 mV to reach a current density of 10 mA cm⁻². It was illustrated that the high valence metal cations under the OER conditions are the active centers. The sXAS spectra demonstrated that the existence of S can assist the formation of high valence Ni under the OER conditions (Fig. 5g and h) to improve the OER activity, while Fe can help to stabilize the S doping. The combination with S reduces the Gibbs free energy for the formation of high valence states of Ni and Fe, and directly influences the reaction pathways, resulting in an enhancement in OER performances.

Wang *et al.* demonstrated a novel *in situ* chemical etching process of Ni(OH)₂ nanosheets followed by a thermal ammonolysis process to fabricate iron-nickel nitride Ni₃FeN supported by pure Ni metal (Fig. 5i-n).⁷⁰ Ni₃FeN is not stable, and thus would be converted partially into NiFeOOH under oxygen evolution conditions, forming an NiFeOOH/Ni₃FeN/Ni heterojunction and showing extraordinarily high activity for the OER in alkaline medium with a very low overpotential of 200 mV at 10 mA cm⁻² and a low Tafel slope of 36 mV dec⁻¹. The result showed that combining NiFe alloys with nitrogen to form the Ni₃FeN/Ni metal nitrides was beneficial for increasing the charge transfer dramatically, resulting in faster charge-carrier transportation and better electronic conductivity.

Here, we summarize the effects of doping different heteroatoms in NiFe alloys. When doping NiFe alloys with metallic heteroatoms, the metallic heteroatoms may generally provide

new active sites and a synergistic effect with nickel and iron atoms to improve the OER catalytic activity. When NiFe alloys are combined with non-metallic heteroatoms, the catalytic site is still the center of NiFe, but the presence of non-metallic heteroatoms tunes the electronic structure around Ni and Fe, which is beneficial to accelerate the charge transport process and increase the average oxidation state of Ni in the composites, thereby promote the water oxidation reaction. Among the heteroatomic doping alloys, high-entropy alloys (HEAs) together with the composition tailoring and the disordered configuration to provide optimal surface absorption energies for catalysis may be the most potential electrocatalysts with excellent OER performances.

2.3 *In situ* formation of oxyhydroxides on NiFe alloy surface

Several studies regarding the origin of the activity for the OER have suggested that the *in situ* generation of oxy-hydroxides (MOOH) after self-reconstruction on the surface under the OER conditions is crucial for the high catalytic activities. Typically, the fast formation of NiOOH in NiFe-based catalysts is most likely dominant during self-reconstruction.⁷¹ As early as the 1980s, Corrigan *et al.* first studied the oxygen evolution behavior of nickel oxide electrodes with Fe impurities. The Fe impurities from the electrolyte co-precipitated on nickel oxide films were discovered to have strong effects on catalyzing the OER. Changing the Fe content could adjust the electrochemical oxidation of Ni(OH)₂ to NiOOH process, and a composite NiFe hydroxide with >10% Fe showed intriguing activities toward OER electrocatalysis with an overpotential of ~200–250 mV at 10 mA cm⁻² and a low Tafel slope of 20–25 mV dec⁻¹.^{72,73} Besides, Stahl's group used operando Mössbauer spectroscopy to provide direct evidence for the formation of FeOOH in the NiFe hydroxide catalyst under steady-state water oxidation conditions.⁷⁴ A recent study suggested that FeOOH nanoparticles (NPs) could greatly enhance the OER catalytic performance of NiFe LDH through strong interfacial interactions, which could facilitate the oxidation of Ni²⁺ in the NiFe LDH to enhance its electrochemical catalytic behavior.⁷⁵ It is worth noting that the *in situ* generation of oxy-hydroxides (MOOH) after self-reconstruction in the NiFe-based catalyst not only happened on the NiFe oxide, NiFe hydroxides and NiFe LDH, but also on NiFe alloy catalysts. For example, Liang *et al.* fabricated robust Ni_xFe_{1-x} alloy (core)-ultrathin amorphous oxyhydroxide (shell) nanowire arrays (denoted as Ni_xFe_{1-x}-AHNAs) *via* a one-step chemical deposition method with the assistance of a magnetic field (Fig. 6a and b).⁷⁶ Specifically, the amorphous layer on the surface of Ni_xFe_{1-x} alloy nanowires could be formed *in situ* as an Ni_xFe_{1-x} oxyhydroxide, which resulted from the inevitable oxidation of the nanowires under the alkaline preparation conditions. The Ni_xFe_{1-x}-AHNA electrocatalyst achieved ultralow overpotentials of 248 and 258 mV to reach large current densities of 500 and 1000 mA cm⁻² with a small Tafel slope of 34.7 mV dec⁻¹ and excellent stability over 120 h, respectively. In the Ni_xFe_{1-x}-AHNA electrocatalyst, the core NiFe nanowires with the crystalline metallic phase can act as good electron conductors to offer catalysts good conductivity.

Fig. 6 Example for the *in situ* oxyhydroxide formation on NiFe alloy surface applied in the OER. (a) Schematic of the synthetic process. (b) SEM image with TEM image in the inset. (c) HRTEM image and (d and e) Ni 2p_{3/2} and Fe 2p_{3/2} XPS spectra of the Ni_xFe_{1-x}-AHNA nanowire array. Reproduced from ref. 76 with permission from the Royal Society of Chemistry, Copyright 2020.

On the nanowire surface, the *in situ*-formed amorphous NiFe oxyhydroxide layer has an ultrathin structure (1–5 nm), which is much thinner than that of the NiFe oxyhydroxide prepared *via* electrodeposition, hydrothermal or chemical deposition methods. The thin nature of the *in situ*-formed amorphous NiFe oxyhydroxide layer can reduce the transfer resistance of electrons in the catalysts, benefit for the binding promotion of OH⁻, and thus enhance the catalytic activities (Fig. 6c–e).

A similar case was reported by Yu *et al.*, who fabricated a three-dimensional core–shell metal nitride catalyst consisting of NiFeN nanoparticles uniformly decorated on NiMoN nanorods supported on Ni foam, which served as an exceptionally active and durable oxygen evolution reaction catalyst for alkaline seawater electrolysis.⁷⁷ The *in situ* Raman spectroscopy technique confirmed the *in situ*-formed NiFe oxides/oxy(hydroxides) on the surface of NiMoN@NiFeN, which undergoes rapid self-reconstruction due to the partial dissolution of FeOOH in KOH solution and formed amorphous NiOOH nanoarrays with a small amount of FeOOH nanoparticles after the OER. Notably, the *in situ*-generated amorphous NiFe oxide and NiFe oxy(hydroxide) layers also played a positive role in

improving the resistance to corrosion by chloride anions in seawater, which contributed to the superior stability during seawater electrolysis.

Briefly, the *in situ* generation of oxy-hydroxides (MOOH) after self-reconstruction on the surface of NiFe alloy catalysts under OER conditions or preparation conditions provides a potential strategy to improve the intrinsic catalytic activities of NiFe alloys.

3. Structure optimization

It is well known that the performance of an electrocatalyst is determined not only by its intrinsic activity, but also the number of accessible active sites. The latter depends heavily on the dimensions, geometry, and structure of the electrocatalyst. The morphology of the catalyst such as spheres,⁷⁸ nanosheet,⁷⁹ nanorods,⁸⁰ nanowires,⁸¹ and nanoboxes⁸² plays a significant role in increasing the number of active sites to enhance its electrocatalytic performances. Compared with zero-, one-, and two-dimensional structures, the three-dimensional porous architecture can provide highly desirable properties and is

propitious to improve the OER catalytic performance considering that it can offer a large surface area, create numerous fast channels for mass transfer and ion diffusion, and increase the active sites. To the best of our knowledge, downsizing NiFe alloy NPs with well-controlled mono-dispersity is one of the most effective ways to realize an increase in the number of active sites. Maximizing the utilization of each active site through the reasonable design of the NiFe alloy structure is envisioned as a prominent but somewhat difficult approach in developing the utmost efficient NiFe alloys for OER catalysis.

3.1 Morphology optimization

3.1.1 Single-atom concept. Single-atom catalysts (SACs) with monodispersed single atoms supported on solid substrates have recently emerged as an exciting class of catalysts, which combine the merits of both homogeneous and heterogeneous catalysts.⁸³ Recently, Wang *et al.* found that Ni single atom sites anchored on graphene are intrinsically poor for the OER, but the interaction between Ni and Fe atoms to form Ni/Fe dual-atom sites significantly increases the OER activity by more than 10 fold.⁸⁴ The formation of the Ni/Fe sites bridged by oxygen atoms with a distance of about 2.7 Å could adsorb HO⁻ ions to facilitate the OER process. Similar results were reported by Cheng *et al.* that both Fe SACs and Ni SACs have poor OER activities in alkaline conditions, while the formation of an atomically dispersed FeNi dual-metallic catalyst resulted in a significant enhancement in their OER activities.⁸⁵ Both the Fe and the Ni atoms were found through XAS analysis to be stabilized by coordinating with nitrogen atoms, suggesting the presence of a nitrogen bridge between the bimetallic Fe and Ni atoms. The N-bridged Fe/Ni atoms are further supported by a negative shift in the Fe L-edges and a positive shift in Ni L-edge compared to the Fe and Ni SACs. These active N-bridged dual Ni/Fe atoms could promote the adsorption and dissociation of the reaction intermediates on the surface of the catalyst and facilitate the OER process, similar to that reported by Wang *et al.*⁸⁴ Besides forming bridged FeNi bimetallic dual-atom active sites for the OER, accelerating the charge transfer

between the Fe and Ni sites is another way to promote the catalytic activity. Liu *et al.* reported a facile high-temperature polymerization route to fabricate porous dual-metal single-atom-doped g-C₃N₄ patches on carbon nanotube bundles (NiFe@g-C₃N₄/CNTs) (Fig. 7a).⁸⁶ The HAADF-STEM and XAFS results confirmed that Ni/Fe atoms were randomly distributed on the surface of the g-C₃N₄@CNT core-shell structure by forming metal-N_x coordination without noticeable aggregation (Fig. 7b and c). The XANES of the Ni L edge and Fe L edge illustrated that the number of unoccupied electron density states increased at the Ni sites, while electron transfer occurred between Ni and Fe (Fig. 7d-g). Briefly, compared with single-metal-doped catalysts, the dual NiFe single-atom-doped g-C₃N₄@CNTs could expose excess metal active sites, good electrical contact and partial charge transfer between the Fe and Ni sites. Through this multi-metal atom strategy, the synergistic effect can be triggered by altering the electronic structure to accelerate the charge transfer and thus promote the catalytic activities. Consequently, the formation of Ni/Fe dual-atom sites not only has the advantages of the high catalytic activity of NiFe alloys, but also the single-atom catalysts (SACs), with their maximum atom-utilization efficiency, high selectivity, and unique properties to increase the number of active sites.

3.1.2 Dimensional control. Dimensional control of NiFe alloys has always been considered a good way to increase the number of accessible active sites. Here, we present two typical examples of the dimensional control for the activity enhancement of NiFe alloys. The first example is one-dimensional NiFe catalysts. One-dimensional (1D) nanostructured materials have attracted wide research attention due to their spectacular physicochemical properties and suitability for studying size-dependent transport phenomena. When used as electrocatalysts, 1D metallic nanorods exhibit obvious advantages compared to the traditional powder electrocatalysts. The high aspect ratio of the 1D nanostructure presents large extended surface areas to provide abundant active sites for electrocatalytic reactions. Furthermore, the 1D-oriented structure offers fast guided charge and mass transfer.⁸⁷ Huang *et al.*

developed a bubble release-assisted pulse electrodeposition method to fabricate NiFe metallic alloy nanotube arrays in one step (Fig. 8a).⁸⁸ Unlike traditional nanotube array fabrication methods, which normally require two steps with the assistance of sacrificial nanowire/nanorod templates,⁸⁹ the bubble release-assisted pulse electrodeposition method is simple, controllable, and capable of creating open-end tubular structures. The nanotube structure (Fig. 8b and c), with inner tube walls available for electrocatalysis, provides larger reaction surface areas and stronger mass-transfer guiding ability than nanowires/nanorods. The NiFe alloy nanotube arrays were demonstrated to be highly efficient and stable bifunctional electrocatalysts for overall water splitting, delivering a current density of 10 mA cm⁻² at low overpotentials of 236 and 100 mV for the OER and HER, respectively. The valence states of both Ni and Fe became more positive after the stability tests, with the increasing dominance of the 3+ state contributed by the active species, NiOOH and FeOOH. Furthermore, it was confirmed *via* DFT calculations that the presence of Fe sites in NiOOH optimizes

the critical adsorption energies of the OER intermediates (OH, O, and OOH), thereby reducing the required overpotentials for the OER.⁵¹ The second example is three-dimensional (3D) NiFe foams with multiscale porous architecture, which were constructed *via* cathodic deposition with the concomitant generation of H₂ bubbles (Fig. 8d–f).⁹⁰ As shown in Fig. 8g, the largest current density was achieved for the Ni₃₀Fe alloy foam with a low onset overpotential of 240 mV. The real active sites were the NiFeO_x formed on the surface of the NiFe alloy foam during water oxidation. The porous framework and the hierarchical structure of the NiFe alloy foam were demonstrated to have a significant effect on exposing the inner catalytic active sites, promoting mass transport, and accelerating the dissipation of the gas bubbles generated during water splitting. In conclusion, designing NiFe alloys into different dimensions is a potential way to provide high surface area, promote fast guided charge and mass transfer and accelerate the dissipation of gas bubbles to enhance the OER performance of NiFe alloys.

Fig. 9 NiFe alloys supported on different conductive substrates.

3.2 Carbon material modification

On one hand, because the large and rough surface of NiFe alloys is directly exposed to the electrochemical environment, their stability needs to be further improved. Accordingly, coating

NiFe alloys with an inert layer such as carbon can avoid direct contact to protect the active NiFe alloys. On the other hand, NiFe alloy nanoparticles easily aggregate, reducing their electroconductibility. Thus, it is an effective strategy to support NiFe alloys on a conductive material to avoid their aggregation and increase their electroconductibility. The different ways to support NiFe alloys on conductive materials are shown in Fig. 9, including NiFe@carbon, NiFe on graphene, NiFe on carbon nanotubes, NiFe on carbon fibers, NiFe on MOF-derived carbon, and NiFe on biomass-derived carbon. Furthermore, the different ways for supporting NiFe alloys on conductive materials result in different catalytic activities.

Here, we begin with the simplest NiFe@C core-shell structure. The core-shelled NiFe@C catalysts, consisting of NiFe nanoparticles with a diameter of 15 nm encapsulated by 2–3 carbon layers, were developed using a one-pot synthetic method by injecting a high-density electrical pulse through NiFe wires with ethanol medium acting as the carbon source (Fig. 10a and b).⁹¹ The core-shelled NiFe@C catalyst displayed outstanding catalytic performances for both the OER and HER in alkaline

solution. The large number of Fe(III) species on the surface of NiFe@C revealed from the XPS analysis, which can act as a positive charge active region, enhanced the partial charge transfer and generated highly active sites (Fig. 10c and d). More importantly, the carbon layers encapsulating the NiFe alloys promoted the electrochemical stability by protecting the alloy nanoparticles from corrosion and/or oxidation caused by the electrochemical redox process at interface between the catalysts and electrolytes. Furthermore, an ultrathin carbon shell on alloy nanoparticles can facilitate electron penetration from the alloy core to the catalyst surface. This unique property modulates the electronic properties of the carbon surface to more favorably adjust the binding energies of reaction intermediates on the catalyst surface, enhancing the catalytic activities for both the OER and HER.

In addition to coating NiFe alloy nanoparticles with carbon layers to form a core-shell structure, the most common way is to support NiFe alloy nanoparticles on layered graphite carbon. For example, Chen *et al.* synthesized FeNi₃ alloy-coupled N-doped carbon (FeNi₃@NC) using chitosan as both the nitrogen and carbon source (biomass-derived carbon). The presence of the N-dopant in the carbon layers increased the degree of defects in the catalyst and was beneficial for the OER performances.⁹² It exhibited a low OER overpotential of 277 mV at 10 mA cm⁻² (Fig. 10e). In the electrocatalysts, the presence of NiFe alloys could significantly enhance the electrical conductivity, and thus fasten the charge transfer, while the large amounts of pyri-N in the carbon layers could improve the

catalyst conductivity and surface wettability (Fig. 10f). In addition, the co-existence of graph-N in the electrocatalyst also helped to improve the diffusion-limited current density. Thus, the exposed edges of the FeNi₃ nanoparticles, the metal-N interface coupling center, and the N-C center all provided active sites and contributed to the excellent electrocatalytic performances. Furthermore, the results also showed that the rational integration of NiFe and carbon layers can exhibit a synergistic effect among the Fe, Ni and NC layers to greatly improve the electrocatalytic activities toward the OER by coordinating their advantages and offsetting their disadvantages.

The cases of NiFe alloys on carbon nanotubes and fibers are similar. NiFe alloy nanoparticles embedded on N-doped carbon nanotubes (NiFe/N-CNT)⁹³ and NiFe alloy nanoparticles anchored on bamboo stick-derived N-doped carbon fibers (NiFe@NCNFs)⁹⁴ both showed similar active roles to enhance the catalytic OER performances. Firstly, the highly active NiFe alloys are synergistically integrated in the nanocomposites through the bifunctional electronic effect, followed by embedding in the conductive shell, which can suppress the agglomeration and dissolution of the inner NiFe nanoparticles. Secondly, the Ni atoms on the Fe-based alloy nanoparticles afford a moderate binding affinity for oxygen molecules and OH⁻ ions, whereas the electron transfer through the graphitic carbon shell can be also enhanced. Thirdly, the N-doped graphitic carbon shells provide both electrical conductivity and durability during the long-term oxygen catalytic reaction.

Fig. 12 Illustration of the electronic modulation and structural design of NiFe alloy electrocatalysts toward efficient OER.

The use of MOF-derived carbon to support NiFe alloys has been reported to provide a large surface area with the coexistence of micropores and mesopores inherited from the MOF precursor. Ding *et al.* designed a three-step route to fabricate

a hollow MOF-derived 3D carbonaceous matrix with randomly loaded FeNi₃ alloy nanoparticles (Fig. 10g and h).⁹⁵ The resulting NiFeC composites exhibited great OER performances with a low overpotential of 269 mV at 10 mA cm⁻². The good OER

Table 1 Overpotential (η) to obtain 10 mA cm⁻² for the oxygen evolution reaction (OER) of NiFe catalysts with composition optimization

Composition optimization	Active roles	Electrocatalyst	Electrolyte	η_{OER} (mV)	Tafel slope (mV dec ⁻¹)	Ref.
Amorphous NiFe alloy	The short-range atomic ordering but long-range disordered structure could increase the active site density, thus improving the charge-transfer rate by providing easy pathways for charges	Amorphous NiFe	1 M KOH	265	24	40
		NiFeIr _x /Ni NW@NSs	1 M KOH	200	44.6	99
		NiFe NTAs-NF	1 M KOH	216	64.5	42
Metastable NiFe phase	The stacking mode of NiFe metal atoms in different crystal phases gives rise to distinct structures and electronic properties, greatly influencing the intrinsic catalytic properties of NiFe metal alloy nanomaterials. The metastable hcp-phase NiFe possesses favorable electronic properties to expedite the OER reaction	Fcc-phase NiFe alloy	1 M KOH	298	51.9	48
		Hcp-phase NiFe alloy	1 M KOH	226	41	51
Metallic heteroatomic doping	The introduction of another metal heteroatom can act as active sites and can further modify the surface electron distribution of a metal or alloy to produce more active sites	FeCoNi	1 M KOH	288	60	100
		NiFeCu	1 M KOH	180	33	61
		NiFeCr	1 M KOH	200	28	62
		High entropy alloys	1 M KOH	263	43	66
Nonmetallic heteroatomic combination	The combination of a non-metallic heteroatom with NiFe tunes the electronic structure around Ni and Fe, which is beneficial to accelerate the charge transport process, resulting in an increase in the average oxidation state of metals, and thereby promote the water oxidation reaction	NiFe phosphide	1 M KOH	260	38.7	68
		NiFe diselenide	1 M KOH	267	67	103
		NiFe nitride	1 M KOH	200	36	70
<i>In situ</i> formation of oxyhydroxide on NiFe alloy	The <i>in situ</i> generation of oxy-hydroxides (MOOH) after self-reconstruction on the surface under OER conditions is crucial active role for the OER	Ni _x Fe _{1-x} -AHNAs	1 M KOH	248 at 500 mA cm ⁻²	34.7	76
		NiMoN@NiFeN	1 M KOH	248 at 100 mA cm ⁻²	58.6	77

activity of NiFeC can be attributed to: (i) the hollow cubic carbon shell with the coexistence of micropores and mesopores in the resultant catalyst provides a large surface area to enable efficient contact between the solid catalyst and the liquid electrolyte and facilitate the diffusion of oxygen and (ii) the porous carbon matrix derived from the MOF can effectively restrict the agglomeration of the NiFe nanoparticles during calcination at high temperature, improve the electron conductivity and facilitate quick electron transfer.

In summary, coating conductive materials on NiFe alloys can avoid their direct contact with the electrolyte and protect the active NiFe alloys from corrosion. It can also prevent NiFe alloys from aggregating and increase their electroconductibility. The conductive material can endow NiFe alloys with both high conductivity and catalytic activity, and the large specific surface area leads to fast electron transfer and ion diffusion and facilitates charge transfer.

3.3 Composite structure

Rationally designing the composite structure of the whole catalytic electrode can enhance the mechanical stability, electron transfer efficiency, ion diffusion rate, reaction kinetics, and

exposure of active sites. Nickel foam (NF) with a large surface, 3D structure and high flexibility has emerged as a leading candidate substrate for NiFe alloys. Jin *et al.* reported a fast one-step method for the electrodeposition of NiFe alloy nanoparticles with NF as the substrate to form a composite electrode.⁹⁶ To increase the roughness and surface area of the obtained NiFe alloy nanoparticles, Ni and Fe chlorides were used instead of the commonly used Ni and Fe sulfate because the chloridion can prevent passivation to accelerate NiFe deposition by replacing the adsorbed oxygen on the electrode. The as-deposited NiFe/NF could be directly used as OER catalysts without further treatment such as adding binders or conductive film. The Ni 2p_{3/2} XPS showed that the proportion of Ni³⁺ and Ni²⁺ increased after the OER test, while the O 1s spectrum revealed that O existed in the form of OH⁻ and O²⁻, suggesting the existence of Ni(OH)₂ and NiOOH. The synergetic effects of the deposited NiFe alloy and NiFe hydroxides formed during the OER enabled both high conductivity and catalytic activity. The large specific surface area due to the 3D skeleton of NF led to fast electron transfer and ion diffusion and the porous structure exposed with more active sites facilitated the charge transfer.

Table 2 Overpotential (η) to obtain 10 mA cm⁻² for the oxygen evolution reaction (OER) of the catalysts with structure optimization

Structure optimization	Active roles	Electrocatalyst	Electrolyte	η_{OER} (mV)	Tafel slope (mV dec ⁻¹)	Ref.
Single-atom conception	The dual-metal atoms stabilized by nitrogen or oxygen bridges can present excess metal active sites, good electrical contact and partial charge transfer between the Fe and Ni sites and facilitate the adsorption and dissociation of the reaction intermediates to promote the OER	HG-NiFe	1 M KOH	310	39	84
		Bimetallic FeNi	0.1 M KOH	430	56	85
		NiFe@g-C ₃ N ₄ /CNT	1 M KOH	326	67	86
Dimensions control	Dimensional control of NiFe alloys is a potential way to provide high surface area, promote fast guided charge transport and mass transfer and accelerate the dissipation of gas bubbles to enhance the OER performance	1D NiFe alloy nanotube array	1 M KOH	236	45	88
		3D NiFe alloy foams	1 M KOH	240	47	90
Carbon material support	Coating conductive materials on the NiFe alloys can avoid the direct contact of NiFe alloys with the electrolyte and protect active NiFe alloys from corrosion. It can also prevent NiFe alloys from aggregating and increase their electroconductibility. The conductive material can provide NiFe alloys with both high conductivity and catalytic activity and the large specific surface area leads to fast electron transfer and ion diffusion and facilitates charge transfer	NiFe@C	1 M KOH	345	57	91
		Ni _{0.5} Fe _{0.5} @N-graphite	1 M KOH	210	62	101
		Ni ₅₀ Fe ₅₀ @N-CNTs	1 M KOH	318	79	102
		FeNi ₃ @NC	1 M KOH	277	77	92
		NiFe@NCNFs	1 M KOH	294	52	94
		NiFeC-800-5	1 M KOH	269	72	95
Composite structure	The composite structure of NiFe alloy with other substances not only can use the active site of the dual component, but also the composite structure of the whole catalytic electrode can enhance the electron transfer efficiency, ion diffusion rate, reaction kinetics, exposure of active sites and mechanical stability, and thus has a great impact to improve the OER performances	NiFe/NF	1 M KOH	191	44.1	96
		NiFe@V ₂ O ₃	1 M KOH	330	51	97
		CoMnP/Ni ₂ P/NiFe	1 M KOH	240 at 50 mA cm ⁻²	60	98

In addition, depositing NiFe alloy NPs on conductive and catalytically active substrates to form a composite structure is also an effective strategy to improve their catalytic performances. Xu *et al.* developed a top-down method to anchor NiFe alloy nanoparticles on the surface of hierarchical nanoporous V_2O_3 nanosheets (Fig. 11a–d).⁹⁷ The NiFe@ V_2O_3 hybrid exhibited excellent electrocatalytic performances for both the OER and HER. When employed as a bifunctional electrode for overall water splitting, NiFe@ V_2O_3 only required a cell voltage of 1.56 V to reach 10 mA cm⁻² (Fig. 11e). The reason for the excellent electrocatalytic performances is that the designed hierarchical nanoporous structure enhanced the specific surface areas and facilitated the mass transfer of the electrolytes and the evolved gases. Moreover, the catalytically active metallic-like V_2O_3 matrix could accelerate electron transfer and provide extra active sites for electrocatalysis.

Bu *et al.* prepared a unique sandwich structure of CoMnP/Ni₂P/NiFe by introducing an Ni₂P interlayer between CoMnP nanosheets and nickel-iron (NiFe) foam to achieve an excellent bifunctional electrocatalyst in alkaline media (Fig. 11f).⁹⁸ It was notable that the hollow 3D NiFe alloy substrate provided a high loading capacity of CoMnP nanosheets, while the continuous low-resistant Ni₂P interlayer between the NiFe substrate and the CoMnP active material yielded an efficient electron transmission channel from the current collector to the active materials (Fig. 11g–i). In addition, the introduction of Ni₂P could modify the electronic structure of CoMnP *via* strong electron interaction and enhance the contact between CoMnP and NiFe. Importantly, the synergistic effect of combining surface and interface engineering in this unique sandwich structure resulted in remarkable OER and HER performances, which was proven using a 1.5 V battery to power an overall water splitting device (Fig. 11j and k). The high bifunctional activity is mainly attributed to the structural design, interface and surface engineering as follows: (i) the 3D hollow NiFe foam provides sufficient loading capacity for the CoMnP nanosheets, which enhances the exposure of active sites; (ii) the Ni₂P sublayer between CoMnP and NiFe foam provides rapid electron pathways to increase the electron transfer; and (iii) the electronic structure of the active sites on the CoMnP nanosheets is modified by Ni₂P *via* strong electron interaction, thus improving the intrinsic activity of the surface active species.

In summary, according to the description mentioned above, the composite structure of NiFe alloys with other substances not only can use the active sites of the dual component, but the composite structure of the whole catalytic electrode can also elevate the electron transfer efficiency, ion diffusion rate, reaction kinetics, exposure of active sites and mechanical stability, and thus has a great impact to improve the OER performances.

4. Conclusions and perspective

The development and use of hydrogen energy is a practical and significant approach for solving various issues associated with the continuous consumption of traditional fuel energy. To date, researchers have focused great interest on water splitting devices for the large-scale and green production of hydrogen.

However, water-splitting is not a particularly efficient technique due to the high energy barrier in the OER process; therefore, designing superior OER catalysts plays a crucial role in water splitting devices. Specifically, NiFe-based materials as OER electrocatalysts have shown excellent performances compared to noble metal-based OER electrocatalysts. Different from other reviews related to NiFe-based catalysts, the present review emphasized the mechanism of NiFe alloy catalysts in alkaline water oxidation and their catalytic active centers.

In this review, based on numerous experimental and theoretical reports, the mechanism of the OER on NiFe alloy catalysts was discussed in depth to emphasize the active roles of NiFe alloy catalysts, suggesting that NiFe alloy catalysts can be promising candidates to achieve optimal adsorption for OER intermediates to enhance the OER activities by electronic modulation and structural design (Fig. 12, Tables 1 and 2). Four types of effective means were proposed to increase their intrinsic activity by electronic modulation as follows: (i) preparing an amorphous phase with short-range order but long-range disorder of NiFe alloys can improve the charge transfer rate by providing easy pathways for charges. (ii) Acquiring the metastable phase of NiFe alloys, which possesses a high energy density and gives rise to distinct electronic states to expose more active sites. (iii) Controllably doping multiple heteroatoms to form high-entropy alloys with high complexity and multiple components can provide more active sites and lead to the effective modulation of the electronic configuration and intrinsically promote the OER kinetics. (iv) Catalyst design to achieve the *in situ* generation of oxy-hydroxides (MOOH) after self-reconstruction on the surface of NiFe alloys under OER or preparation conditions, which play a crucial active role due to their high catalytic activities and can reduce the transfer resistance of electrons within catalysts. This is also beneficial for the binding promotion of OH⁻, and thus the enhancement of the catalytic activities. Meanwhile, four types of effective means are also proposed to increase the number of active sites by structural design as follows: (v) constructing dual-metal single atoms can expose excess metal active sites, good electrical contact and partial charge transfer between the Fe and Ni sites. (vi) Constructing specific nanostructures of NiFe alloys can increase the surface density of active sites. (vii) Employing carbon materials as a support can promote the transportation of ions and electrons. (viii) Composite structures can take advantage of all the composite compositions and structures to form a composite catalytic electrode, which can enhance the mechanical stability, electron transfer efficiency, ion diffusion rate, reaction kinetics, and exposure of active sites.

Obviously, with the deepening of research and the development of analysis technology, there are still many questions that need to be emphasized. (i) When designing OER catalysts, researchers often tend to focus on decreasing the overpotential, but ignore the stability. Thus, it is highly desirable to fabricate NiFe alloy catalysts with a low overpotential and long-term stability. (ii) The majority of the as-prepared NiFe alloy electrocatalysts only exhibit excellent properties under alkaline conditions as they dissociate easily under acidic conditions. Thus, greater attention should be paid to fabricating NiFe alloy

catalysts that can function under universal pH. Meanwhile, designing bifunctional NiFe alloy catalysts for both the OER and the HER can solve the problem of poor compatibility during overall water splitting. (iii) The catalyst phase appears to change during the OER process, and thus *in situ* characterization techniques, atomic scale characterization techniques and DFT calculations are needed to identify the true active sites present in NiFe alloy materials to dissect the mechanism and reaction pathway for water splitting and the precise structure–activity correlation.

Clearly, NiFe alloy electrocatalysts deserve our continued attention. Combined with various experiments, characterization and DFT calculations, a deeper understanding of the relationship among electronic modulation, structural design and oxygen evolution reaction performance may be achieved. Prospectively, this understanding will provide more opportunities for the rational design of NiFe alloys electrocatalysts and offer insight into the nature of alloys catalysts and NiFe-based catalysts, not only for the OER, HER and ORR, but also for other important catalytic systems.
