ABSTRACT

This paper compares different power-to-methanol process configurations encompassing electrolyser, adiabatic reactor (s) and methanol purification configurations. Twelve different power-to-methanol configurations based on direct CO₂ hydrogenation with H₂ derived from H₂O-electrolysis were modelled, compared, and analysed. High temperature solid oxide electrolyser is used for hydrogen production. Fixed bed reactor is used for methanol synthesis. The aim of the paper is to give detailed comparison of the process layouts under similar conditions and select the best performing process configuration considering the overall methanol production, carbon conversion, flexibility, and energy efficiency. ASPEN PLUS® V11 is used for flowsheet modelling and the system architectures considered are the open loop systems where methanol is produced at 100 kton/annum and sold to commercial wholesale market as the final purified commodity. Further optimization requirements are established as targets for future work. Three options of power-to-methanol configuration with methanol synthesis from CO₂ hydrogenation are proposed and further evaluated considering process flexibility. From the evaluation, the series-series based configuration with three adiabatic reactors in series performed better in most parameters including the flexible load dependent energy efficiency.

Keywords: Power-to-Methanol System Configurations, Process Design, Process Integration, Solid Oxide Electrolyser.

34 1. INTRODUCTION

35 Investment in renewable energy has been resilient to the Covid-19 pandemic.¹ With the ongoing transition
36 to renewable energy sources particularly variable solar and wind, and the need for cleaner fuel derivatives,
37 chemical energy storage stands central as the best potential solution to meet these sustainability goals.
38 Methanol is a versatile chemical intermediate and due to its ease in handling, it is a robust renewable
39 hydrogen carrier.²⁻⁶ Recent study by Hank et al. investigated the potential to transport renewable hydrogen
40 using methanol, ammonia, liquid organic hydrogen carriers and methane.³ The study reiterated the
41 significant potential of methanol to transport large amount of green hydrogen over long distances.³ The fact
42 that various value-added downstream chemicals can be produced from methanol (*i.e.*, the power-to-fuels),
43 its ease in handling and the fact that it can be used directly in the fuel cells to produce electricity (*i.e.* the
44 power-to-power architecture) makes it attractive.

45 Considering plant-to-planet analysis of green methanol via using planetary boundaries tool, González-
46 Garay et al. discovered that the potential damage that green methanol can cause to the freshwater use,
47 nitrogen and phosphorous flow are negligible when compared to the positive effects it will have on energy
48 imbalances, CO₂ emission reduction and ocean acidification.⁷⁻⁸ According to Moili et al. the hydrogen
49 stored in methanol and methane processes are 85.3% and 78.2 %, respectively, thus indicating the good
50 storage potential of methanol.⁴ However, the methanol economy requires favourable policy directions.⁴⁻⁶
51 In this front, majority of countries in the European Union (EU) as well as China have already announced
52 ambitious plans to develop commercial scale renewable methanol plants by 2030.⁵ Renewable Energy
53 Directive II (RED II) of the EU requires that 14% of renewable energy derived fuels, including green
54 methanol, be part of the transport sector by 2030.⁹

55 1.1 Recent progress in PtMeOH System level evaluation

56 Growing efforts are devoted to the so-called PtMeOH chain as a candidate process for sustainable methanol
57 production via CO₂ valorisation and with hydrogen produced from renewable energy resources e.g. wind
58 and solar via the electrolysis route.¹⁰⁻¹⁶ Electrolysis technologies encompasses alkaline water-based
59 electrolyser (AWE), polymer exchange membrane (PEM) and solid oxide electrolyzers (SOEC). Numerous
60 studies have evaluated the energetic and techno-economic feasibility of PtMeOH.^{2-3, 17-24} Rivera-Tinoco et
61 al. deduced that SOEC-based PtMeOH has a higher energy efficiency (~54.8 %) than PEM-based
62 PtMeOH.²¹ Hank et al. evaluated the transport potential, techno-economics, and energy efficiency of PEM-
63 based PtMeOH and deduced that the process has an energy efficiency in a range of 40–44% comparable to
64 the power-to-methane process.³ Zhang et al. evaluated the techno-economics of SOEC-based biomass-to-
65 methanol process and deduced that an energy efficiency of 66 % can be achieved from this process and
66 highlighted a trade-off between the system efficiency and its production cost.²² However, biomass-based

67 processes are limited by biomass feedstock availability.²⁰ Zhang et al. investigated the techno-economic
68 optimization of the SOEC-based PtMeOH process and similarly observed that there is a trade-off between
69 the energy efficiency and the production costs.²² Bos et al. investigated the techno-economics of a 100 MW
70 wind-based PtMeOH plant with hydrogen produced from AWE and concluded that the process has an
71 energy efficiency of 50%.¹⁷ Al-Kalbani et al. compared the environmental performance of fossil fuel-based
72 and renewable energy-based PtMeOH, and their findings depicted that renewable energy-based PtMeOH
73 is attractive from an environmental perspective.¹⁸ The main conclusion from these studies points to high
74 energy demands and high hydrogen production and electrolyser capital costs as the major techno-economic
75 feasibility barriers.³ The availability of power determines the quantity of hydrogen that can be produced
76 and therefore the optimal capacity and system configuration.^{7,17} It also emanates from these studies that the
77 SOEC is an attractive technology from the perspective of energy efficiency and for coupling with
78 exothermic processes such as methanol production process, although further improvements on the SOEC
79 technology (e.g. flexibility) is still required to make its application in renewable PtMeOH more competitive.

80 On the other hand, these studies highlighted the required improvements in carbon capture technologies,
81 particularly from the confines of energy penalty and costs reduction.^{7,17} According to Bos et al., the
82 methanol synthesis loop is dominated by feed compression and the key to optimizing the costs and
83 productivity is to find the favourable ratio between the reactor size(s) and compression requirements such
84 that the reactor operation pressure and cost of compressors remains optimized.^{9, 17} The latter approach is
85 limited by the trade-offs between pressure (i.e. feed compression duties) and conversion due to
86 equilibrium.⁷ An alternative is to reduce the recycle compression by increasing the single pass conversion,
87 but according to González-Garay et al. and Alsuhaibani et al. this strategy has limited impact on profitability
88 relative to decreasing the overall reactor pressure.^{7, 23} Thus efforts in finding cheap and easy to scale
89 catalysts that operates efficiently at lower pressures (<50 bar) shall not cease and their effects will become
90 more dominant (~24.4% share of the total costs) when power-to-methanol is already economically feasible.⁷
91 Furthermore, a combination of economically effective yield and pressure needs to be identified.⁷

92 It is also evident from the highlighted studies that, recently, the system level optimization has emerged as
93 a new paradigm shift needed to improve the economics of the process.²⁴⁻²⁹ To accelerate technology
94 readiness and techno-economic improvement of PtMeOH, several demonstration projects have been
95 implemented and some are being planned.²⁶ Nonetheless, availability of data from demonstrated systems
96 remains scarce and difficult to access. On the other hand, modelling efforts in this direction have thus far
97 been directed to a single objective or only two objectives i.e. energy efficiency and production costs. Thus,
98 optimized process flowsheets that enhances the CO₂ and H₂ conversions, energy efficiency, process
99 economic (lowering production costs and/or capital), flexibility and reduce CO₂ emissions and system

100 complexity are required.³ Due to low conversion of the direct CO₂ hydrogenation over the Cu/ZnO/Al₂O₃,
101 GhasemiKafrudi et al. optimised the process recycle flow to improve the performance.²⁴ They considered
102 different process parameters, including temperature, pressure, and GHSV, to reduce the recycle, energy
103 consumption and greenhouse gas emissions of the CO₂ hydrogenation process. Furthermore,
104 GhasemiKafrudi et al., investigated the effect of changes in the hydrogen injection as make up gas, applying
105 two reactors, inert gases, moisture in the feed, the use of dry hydrogen and the recycle stream on methanol
106 yield.²⁴ Their results showed that having two reactors with intermediate dehumidification in series and
107 adding hydrogen as make-up at the inlet of the second reactor increases the methanol yield by a factor of
108 1.8.²⁷ However, the authors also deduced that if one reactor with recycle is used, the resultant methanol
109 yield is almost double when compared to the case of one reactor with no recycle.²⁴ Finally, GhasemiKafrudi
110 et al., concluded that by just modifying the catalyst type and total amount (decrease slightly e.g. in their
111 case; total amount =865kg) and increasing the inlet temperature (e.g. in their case to 209 °C), the recycle
112 flow reduces by almost 38%.²⁴ Moioli et al. and Lee et al. have already established that for a CO₂
113 hydrogenation on Cu/ZnO/Al₂O₃ based catalyst, and for both small scale and commercial scale (~100
114 kton/annum), three cascade fixed-bed reactors are optimal.^{4,14} Lee et al. deduced that a configuration with
115 three reactors in series, having intermediate cooling and separation of methanol/H₂O between the reactors
116 is optimal in-terms of profit (from a deficit of \$4.3 to \$2.5 profit per ton) and CO₂ conversion (~52%).¹⁴
117 However, Lee et al. using a process superstructure and techno-economic optimization methods investigated
118 the best configuration that optimizes the profit for the two step CO₂ hydrogenation process in which both
119 CO₂ and CO participate as carbon sources in hydrogenation reactions to methanol and focusing only on the
120 synthesis and purification step instead of the direct CO₂ hydrogenation process as will be considered in this
121 study.¹⁴ Furthermore, the superstructure optimisation approach tends to discard the suboptimal flowsheets
122 following set objectives and constraints without giving further details as to why the suboptimal process
123 underperforms and the possibility of improving it further.²⁷

124 More recently, Chiou et al. investigated six different configurations for the PtMeOH focusing on single
125 stage and multistage series reactor(s) connections with adiabatic and non-adiabatic (with co-current
126 cooling) reactor type.²⁸ Their study focused on design, optimisation, control, techno-economics, and
127 environmental aspects of the process considering a small scale (20 kton/y) plant capacity. They reached the
128 conclusion that two reactors with first stage non-adiabatic (with co-current cooling) and second stage
129 adiabatic reactor type in series with inter-stage cooling and separation of methanol and water was more
130 economically attractive (with a minimum selling price of methanol of 998US\$/ton and carbon tax of
131 283US\$/ton) and showed better performance. From this, they devised a control strategy aimed at handling
132 the throughput and compositional disturbances for their proposed configuration. The rejection of two kinds
133 of compositional disturbances i.e. (i) the 5% N₂ and (ii) the H₂ impurity were investigated. Their control

134 strategy allowed the rejection of both compositional disturbances within 5h. It was noted that increases in
135 N₂ impurity composition deteriorates the reaction kinetics and increases the purge rate which reduces
136 methanol production rate with higher loss of CO₂ and H₂. Thus, to maintain the single pass conversion, H/C
137 ratio will have to be increased. The authors however did not investigate any full integrated process with
138 electrolyser, parallel-series configuration, and the three-stage reactors with intercooling, nor the detailed
139 load change flexibility of their system.

140 **1.2. Recent progress in PtMeOH process flexibility**

141 Production processes are prone to stochastic variation for example in system input parameters, internal
142 process parameters and environmental factors.³⁰ A degree of process flexibility helps to deal with these
143 challenges. The level of process flexibility affects the economic gain of the process and the selection of the
144 right conditions (i.e. parameters, location, capacity, etc.) in which the process operates economically.³⁰⁻³³
145 In this paper, flexibility refers to the ability to handle the changes in the feedstock composition/flow or
146 adjustments to other changing boundary conditions in order to adapt the plant operation to the changes in
147 the energy or material supply.³⁴ It is well-known that the electrolyser, in particular the PEM type which is
148 suitable for rapid start-up, can provide good flexibility.^{32,35-36} Lange et al. recently gave a good technical
149 review of the state of the art of the electrolyser technology's flexibility including the SOEC technology
150 which will be considered in this study due to its high efficiency.³⁶ Lange et al. deduced that the SOEC can
151 provide a broad range of load flexibility (-100% to 100 %), but this is countered by its long cold-startup
152 time (~60min).³⁶ However, efforts are being made on the front of improving the performance of the
153 materials for the SOEC cells/stack to allow more flexibility and shorten the start-up time without incurring
154 severe cell damage.³⁶⁻³⁷ The recent results such as in the work of Li et al. showed great potential of the
155 future of the SOEC in handling flexibly the intermittent renewable energy supply with reduced start-up
156 time.³⁷

157 In a coupled electrolysis-methanol synthesis system, intermediate gas (hydrogen and CO₂) storage under
158 intermittent conditions may be needed unless the reactor operates flexible. If the reactor has a wide tolerance
159 to variations in the operational parameters, it is referred to as the load flexible reactor. The load range of
160 the catalytic reactor is a function of chemical reactions, transport rate, catalysts, and reactor design.³² The
161 attainable load flexibility of the methanol reactor section has not been investigated, at-least intensively.<sup>31-
162 33</sup> At the present, to the author's knowledge, only INERATEC GmbH has expressed interest to investigate
163 and scale-up the flexible modular micro-structured reactors. Considering the case of variable renewable
164 energy-based processes, flexibility is typically achieved by over-sizing the main process equipment to
165 account for variability in the load. The size of the equipment directly influences the propagation of
166 disturbances within the unit and the bigger the size, the smaller the influence of disturbances on process

167 variables. However, the load range of the reactor is also limited by operational issues such as maximum
168 temperature rise and ability to achieve autothermic control i.e. in which the reactor outlet is used to heat the
169 feed (via feed-effluent heat exchanger concept).³¹ The heat of reaction is, with careful heat management,
170 generally enough to heat the feed to the methanol synthesis reactor(s) and/or distillation column, thus
171 allowing the system to operate autothermally i.e. achieving energy self-sufficiency without external
172 heating/cooling. In cases where the reactor feed stream is not sufficiently heated, the reaction rate will
173 decrease and thus rendering low outlet temperature, which in effect results into lower inlet temperature and
174 consequently the reaction halts completely. According to the study on fixed bed reactors performed by
175 Zimmermann et al., with methane as an example, the step responses typically implemented by switching
176 from one steady-state to another were found to be the worst-case load change policy due to the existence
177 of unfavourable behaviour such as temperature overshoot and conversion drops.³⁸ Proper design of the
178 network structure can help achieve necessary flexibility without additional oversizing of the equipment.³⁹
179 According to Grossmann & Morari, flexibility cannot be simply achieved by ad hoc addition of equipment
180 or oversizing but by systematic design techniques.⁴⁰

181 Rinaldi & Visconti assessed the steady state and transient performances of a multi-tubular fixed bed reactor
182 for methanol production from biogas.⁴¹ Their modelled system had a methanol synthesis reactor, a flash
183 unit, and accounted for the unconverted gas recycle. The novelty of their conceptual work was to assess the
184 possibility to run a multi-tubular methanol synthesis reactor flexibly, i.e., using the carbon dioxide from
185 biogas and renewable H₂ in order to increase methanol productivity when the process is economically
186 feasible. In their work, the investigation of the methanol synthesis multi-tubular reactor is conducted
187 considering the impacts, on methanol productivity, temperature profile and transient behavior, of the two
188 operating conditions i.e. (i) when the cost of green hydrogen is high, the excess of CO₂ in the biogas is
189 vented and the reactor is fed with CO₂-lean syngas only; (ii) conversely, when affordable renewable H₂ is
190 available, CO₂ is co-fed into the reactor along with this affordable green H₂.⁴¹ These authors compared a
191 1D and 2D model in terms of its ability to better predict the temperature and production profile.⁴¹ They
192 deduced that the concerned reactor manages well both operating conditions with steady state reached within
193 a few hours when switching from one condition to another and that 2D model are better suited to predict
194 the temperature and methanol production profile. Moreover, they also highlighted that reducing the number
195 of tubes (equivalent to the reducing catalyst amount and measured using GHSV) instead of the reactor
196 length is preferred especially for small scale processes. Reducing the length of the reactor can lead to
197 unacceptable hot-spots from the resultant worsening of the convective heat transfer and reduced selectivity
198 to methanol. When the length of the reactor is shortened, the thermal peak is achieved at higher
199 temperatures, and the gaseous stream remains mostly in the kinetic regime to near the end of the reactor.⁴¹

200 This was prevalent when syngas is fed with and without co-feeding the CO₂ and H₂, and when the length
201 of the reactor was decreased below half (up to ¼) of the original length.⁴¹

202 Furthermore, Svitnič and Sundmacher investigated the effect of flexibility of the methanol synthesis process
203 on the levelized cost of methanol (LCOM).⁴² In their finding, the flexibility gains are most prominent for
204 the designs with a single source of renewable energy (either solar or wind) leading to reduction of costs of
205 more than 10%. This gain is significantly reduced for the design with combined solar and wind resources,
206 as the complementary availability of renewable resources allows to better sustain stable operation of the
207 chemical processes, reducing the influence of flexibility to 5.1%. Moreover, the authors deduced that the
208 flexible operation of the methanol synthesis has a stronger effect on the reduction of LCOM, where for the
209 design with a single renewable resource it delivers a roughly 4-times larger reduction of LCOM.

210 More recently, Qi et al. investigated different strategies for flexible operation of the power-to-X processes
211 coupled with renewables using PtMeOH as a reference.³³ The strategies they compared involved the use of
212 the energy buffers i.e. the hydrogen intermediate storage, liquid CO₂ energy storage as a Carnot battery,
213 and Li-ion battery storages. In considering the latter they generated nine process configurations with
214 islanded, grid-assisted only, and grid-assisted bidirectional connections for allocation of energy. Qi et al.
215 considered a combination of solar and wind energy as well as grid electricity purchase.³³ The configurations
216 with grid-assisted bidirectional connections resulted into the most cost-effective way for flexible operation
217 of the power-to-X and the lowest levelized cost (~479.4 US\$/ton) was achieved when the Carnot battery
218 was used. However, this is still more expensive than the methanol produced from autothermal reforming of
219 natural gas which can reach a cost of 285.6US\$/ton and thus indicating that further research and
220 development is needed to make renewable methanol production cost-competitive with other methods. In
221 addition, some trade-offs were observed amongst the performance indexes which indicate that there is no
222 single best solution but rather more case dependent solutions. Moreover, studies are required that
223 incorporate the dynamic modelling of the energy buffer and the electrolyser to account for the factors such
224 as the time varying energy efficiency and the limitations on power ramp-up.³³ Process operation can
225 influence the design of the process and hence the flowsheet. Compared to investigations focusing on
226 methanol synthesis catalyst improvements, studies focusing on PtMeOH reactor design, process
227 configurations and process flexibility are very few. The objective of this paper is to model and compare
228 different PtMeOH process layouts under steady state and dynamic conditions with the consideration of their
229 process flexibilities.

230 **1.3 Statement of originality**

231 The originality of the work in this paper lies in the comparative flexibility analysis of different integrated
232 methanol synthesis system configurations comprising parallel-series and series-series connections. Twelve

233 integrated flowsheets (including co-electrolysis and the electrified reverse water gas shift (e-RWGS)
234 system) based on SOEC, methanol synthesis and purification steps are contrasted to assess their
235 performance in terms of energy efficiency, production rate, and material conversion. In addition, the better
236 performing CO₂ hydrogenation-based flowsheets are assessed under dynamic mode for their flexibility and
237 to answer the following questions:

- 238 1) What is the feasible (with minimum sophisticated equipment) load-change flexibility window?
- 239 2) What is the effect of the load change in the parallel-series and series-series-based configurations?
- 240 3) How do the energy efficiency and conversion in the mentioned flowsheets design changes with the
241 change in the load?

242 Candidate PtMeOH configuration(s) with methanol synthesis from CO₂ hydrogenation is proposed.
243 Furthermore, optimization requirements are established as targets for future work. The paper is structured
244 as follows: Section 2 gives the base content and approach to modelling, Section 3 gives the detailed results
245 and discussion, Section 4 concludes the work and Section 5 give recommendations for future work.

246 2. PROCESS SYNTHESIS AND MODELLING

247 Twelve different flowsheets are synthesized and simulated (see section 2.2.2 table 6 and supplementary
248 material section A2 for more details) under steady state conditions in Aspen Plus® V11 and out of the
249 twelve, three are selected for flexibility assessment under Aspen Dynamics V11 platform. Table 1 shows
250 the assumptions pertaining feed conditions. The system's capacity is designed to store about 162 MW of
251 renewable electricity from either wind or Solar PV farm. This is in scale of a commercial size plant.⁴³⁻⁴⁵ For
252 all flowsheets, the SOEC configuration was left unchanged, however the methanol synthesis section
253 configuration was modified to generate twelve different process configurations. Following the findings of
254 Samimi et al. on the possibility to enhance the production rate of methanol with exclusion of inert in the
255 feed, inert are thus neglected in this study.⁴⁶

256 Table 1: Feed conditions.

Raw materials	Temperature(°C)	Pressure (bar)	Flowrate (kmol/hr)	Composition (mol %)
CO ₂	25	1.0	401	100
H ₂ O	25	1.0	1232	100
Sweep gas (oxygen)	25	1.0	31	100
Steam electrolysis product H₂ feed stream to MEOH unit				
H ₂	35	5.0	1212.5	98.8
H ₂ O	35	5.0	14.3	1.2
Co-electrolysis product syngas feed stream to MeOH unit				
H ₂	35	5.0	1212.5	74.3
CO ₂	35	5.0	105	6.4
CO	35	5.0	296	18.1
H ₂ O	35	5.0	19.3	1.2

257

258 The exclusion of inert allows setting the lowest possible purge as detected by the system control
259 parameters.^{9, 47} Recycle ratio is an effective control parameter of the process (particularly the reactor)
260 productivity and temperature.⁴⁶ It is also critical to highlight that the dynamic modelling of the SOEC to
261 ascertain its capability is beyond the scope of this work. Rather the focus on dynamic modelling is placed
262 on the downstream reactor configurations to establish their flexibility.

263 2.1 SOEC modelling

264 The electrochemical model to simulate the SOEC was implemented in ASPEN PLUS® V11 in the
265 FORTRAN routine with the use of design specifications and calculator functions. Water, sweep-gas
266 (oxygen) and electricity are the primary feeds to the SOEC unit. The thermodynamic model used in
267 modelling the electrolysis is the Redlich-Kwong Soave equation of state (EOS) with modified Huron-Vidal
268 mixing rules (RKSMHV2).⁴⁸⁻⁵⁰ The main electrochemical model is a function of product species, which are
269 electrochemically active i.e. $i=H_2$. The net voltage is expressed by equation 1 below:

$$270 \quad E_i = E_{nerst,i} + E_{act,i}^{her} + E_{act,i}^{oer} + E_{ohm,i} + E_{mic,i} \quad (1)$$

271 Where $E_{nerst,i}$ is the Nernst potential, $E_{act,i}$ refers to the over-potential due to activation of electrochemical
272 reactions, $E_{ohm,i}$ refers to the ohmic over-potential and $E_{mic,i}$ is the interconnect voltage losses. The
273 system is assumed to operate at thermoneutral stack voltage and under steady state, thus equation 2 is used
274 as the main equation to calculate the thermoneutral energy.

$$275 \quad E_{tn} = \frac{\Delta H_r}{I_{tot}} = E_i \quad (2)$$

276 Where ΔH_r is the heat of reaction, and I_{tot} refers to the total current (A). According to Giannoulidis et al.
277 it is advantageous from the perspective of the SOEC energy efficiency to operate the unit at low pressure
278 (<10 bar).² For the selected operating conditions, thermoneutral operation is achievable.^{45, 51} Generally, the
279 planar O-SOEC is operated in the temperature range of 150 °C – 950 °C and pressure range of 1–8 bar.^{2, 52–53}
280 The SOEC operating under co-electrolysis conditions can already produce syngas at ratio of 1.5 to 3.5.⁵³
281 The SOEC unit capacity is designed for 109 MW considering the SOEC operating under steam electrolysis
282 only. However, for the co-electrolysis based SOEC unit capacity only 134 MW is required to produce the
283 syngas given in Table 2. Table 2 shows the input parameters used in the modelling of the SOEC unit.
284 Generally operating the SOEC at higher temperature lowers the electricity requirements and hence increases
285 the energy efficiency. The choice of temperature is a reasonable compromise between allowable
286 concentration over-potential, ohmic over-potential and possibility of achieving thermo-neutral point
287 operation.

288

289 Table 2: SOEC operating conditions and parameters for steam and co-electrolysis

Parameter	Value	Unit
Steam inlet temperature of SOEC	850	°C
Air inlet temperature of the SOEC reactor	850	°C
SOEC stack temperature	850	°C
Reactant utilization	70	%
H ₂ cathode inlet recycle	10	%
Operation pressure	5.0	bar
Stack consumption	29.7	kWh/kgH ₂
Hydrogen production	2827	kg/h
Syngas production	15360	kg/h
Syngas ratio (methanol feed)	2.2	-
LHV of syngas	25	MJ/kg

290

291 Typically, near or at thermoneutral point, high electrolysis efficiency and minimum sweep gas flowrate are

292 achievable.² This makes operating the electrolyser at thermoneutral point attractive.^{2,54–55} Figure 1 illustrates

293 the SOEC model flowsheet for steam electrolysis implemented in ASPEN PLUS. Figure 2 illustrates the

294 SOEC model flowsheet for co-electrolysis implemented in ASPEN PLUS. For steam electrolysis (see

295 Figure 1), demineralized water (stream WATER) is first pumped to increase its pressure to SOEC operating

296 pressure, then vaporised and superheated in a cascade of heat exchangers, and mixed (via CATHOD-M)

297 with cathode feed recirculation (i.e. stream H₂-Recycle stream) which contains 10 mol% of hydrogen.^{56–60}

298 The fraction hydrogen is recycled to prevent electrode (i.e. Ni-YSZ) re-oxidation.⁵⁶ The composition of

299 steam in the SOEC feed (i.e. stream SOEC-FEE) is maintained above 90% to prevent starvation at the

300 electrode, which may cause cell damages. The SOEC cathode is modelled using RSTOIC, using the

301 conditions in Table 2 and the feed steam utilization factor (i.e. in the SOEC-C unit) is assumed to be 70%.

302 The product stream (i.e. stream PRODUCT-1) containing oxygen, hydrogen and unconverted water of the

303 SOEC cathode (SOEC-C) is separated in the electrolyte (i.e. ELECTROL) into PRODUCT-2 and

304 PRODUCT-3. Stream PRODUCT-3 contains only water and hydrogen, and it is split (i.e. SPLIT) into

305 product stream containing wet hydrogen (i.e. stream PROD-4) and recycle stream (i.e. H₂-RECYC). Stream

306 PROD-4 is used to pre-heat the feed stream, and it is ultimately cooled and fed to the separator block (i.e.

307 WATER-SEP) in which a significant quantity of water (i.e. stream WWATER) is removed (discharged or

308 recycled) and wet hydrogen at 98.8 mol% is fed to the methanol synthesis section. Stream PRODUCT-2

309 contains only oxygen. The cascade heat exchanger network is used to recuperate the heat from the effluent

310 streams for the purpose of generating superheated steam at cheaper cost. Sweep gas (i.e. stream SWEEP-

311 GA) is assumed to contain only oxygen and is first compressed (via COMP-1) to SOEC pressure, heated

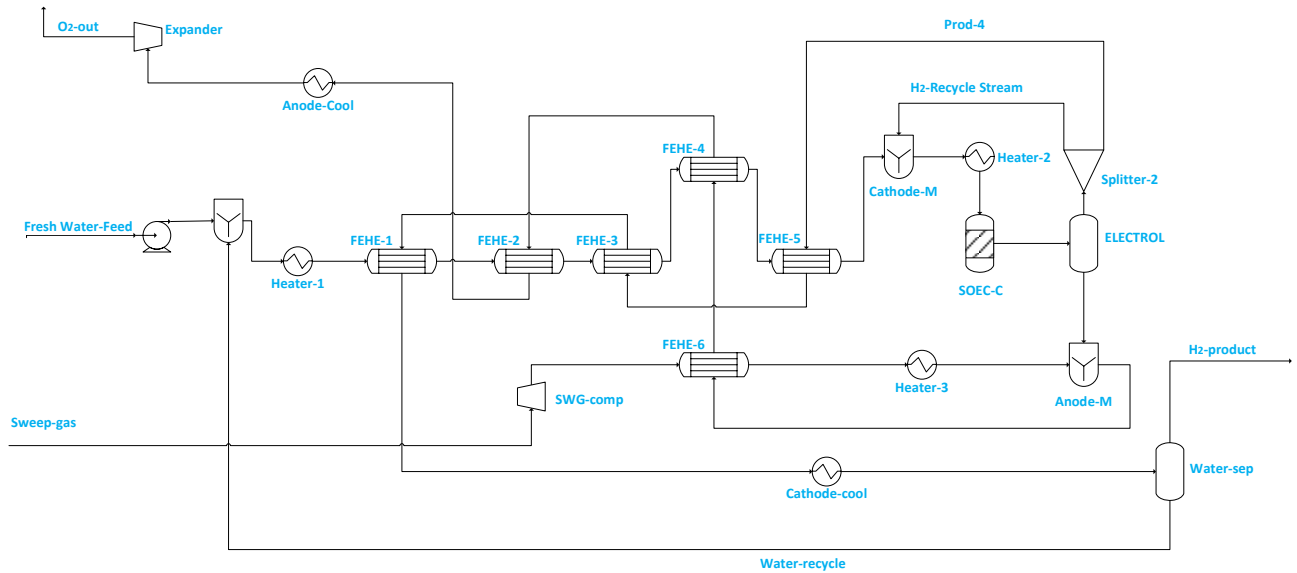

312 (via FEHE 2, HEATER 2) to SOEC temperature and fed to anode side (i.e. modelled as ANODE-M) of the

313 SOEC unit to remove the oxygen produced during electrolysis. The removed oxygen is then used in the

314 cascade heat exchangers to preheat steam, after which it is then cooled and expanded to atmospheric

315 conditions before being discharged or alternatively sold or sent to another process (i.e. stream O2-DISCH).

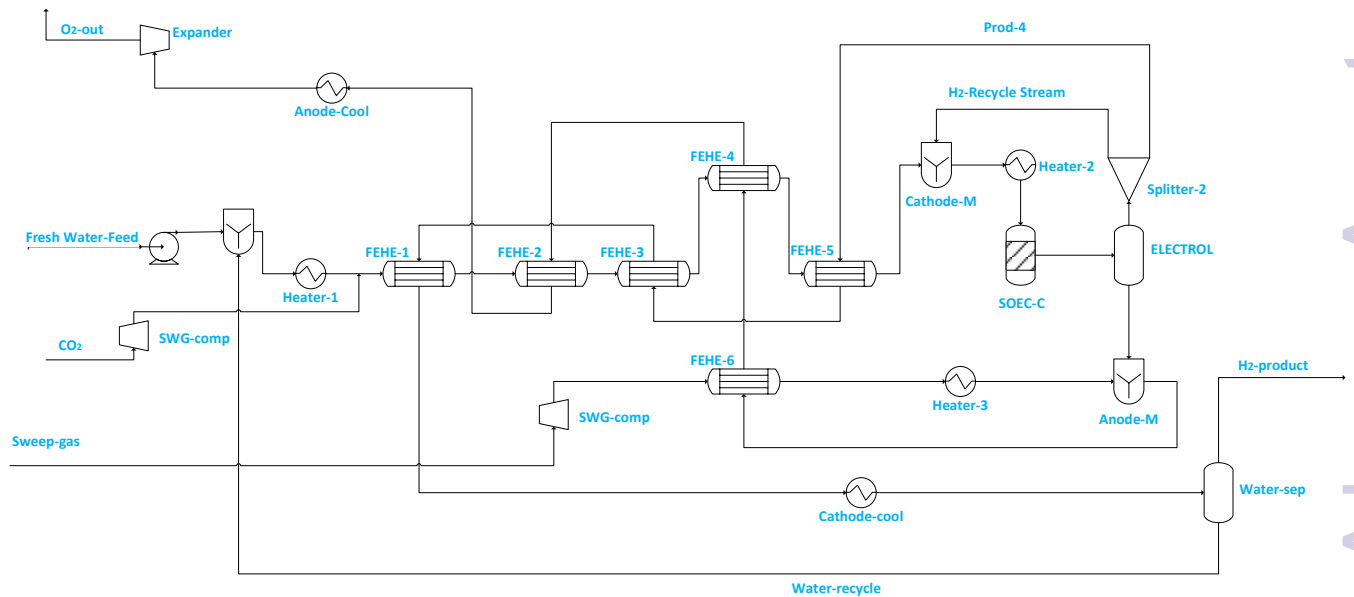

316

317

Figure 1 Illustration of the SOEC unit used for steam electrolysis in ASPEN PLUS®.

318

319

Figure 2 Illustration of the SOEC unit used for co-electrolysis in ASPEN PLUS®.

320 The use of oxygen (recirculated) as a sweep gas manages possible overshoot in the over-potential; therefore
 321 allows for higher energy efficiency operation of the electrolyser. During the start of the process, oxygen is
 322 assumed to come from its storage tank, while during operation it can be recirculated from the anode with
 323 some stored or sold to end users. It is noted beforehand that the use of oxygen may increase the exergy
 324 destruction, but the difference between the exergy efficiency when steam or air is used as sweep gas is
 325 expected to be marginal, with steam as sweep gas having the exergy efficiency which is ~1% more than
 326 that of oxygen.^{47,57} In addition, using oxygen as a sweep gas allows the production of pure oxygen which
 327 can be sold to market.^{47, 57}

2.2 Steady state: reactors and separation modelling

Both CO₂ and H₂ feed streams are compressed to 78 bar using multiple compressors each with an isentropic efficiency of 75% for the steam electrolysis-based PtMeOH. For the co-electrolysis-based system, the syngas feed is compressed in a two-stage compression system to 78 bar with same isentropic efficiency. Considering safety aspects as it would be necessary in real plants, the compression ratio is kept at 3 and inter-stage cooling is included. The temperature of the feed stream to reactor(s) was set to 210 °C.⁶¹ The inlet temperature is in a typical range of an optimised industrial methanol reactor⁶¹, a higher inlet temperature can result in a higher outlet temperature and a lower methanol yield, particularly for the adiabatic reactor(s). In addition, the lower limit for allowable inlet temperature is defined by the catalyst, and for the commercial copper-based catalyst it is around 190 °C.⁶² Commercial Cu/ZnO/Al₂O₃ catalyst is used in this study. Reactor (s) is modelled as an adiabatic reactor(s). Table 3 gives the properties of adiabatic reactor(s) modelled as a plug-flow (RPLUG) and those related to the catalyst. Adiabatic reactors have lower cost relative to the water-cooled and gas-cooled reactors due to their simple structural designs.⁶² The advantage of adiabatic reactors is that under nominal steady state conditions their size is very small, thus their over-sizing slightly affect the capital cost.⁶³⁻⁶⁵ This indicates their potential in small scale PtMeOH processes as well.⁶² The reactor size was selected to be large enough such that the effluent from the reactor is near equilibrium.⁴⁷ Redlich-Kwong-Soave equation of state with modified Huron-Vidal mixing rules (RKSMHV2) was used to model the reactor(s), auxiliaries and to calculate the thermodynamic properties of the streams (refer to Section A1 of the Supplementary Material). After separation of methanol and water using a flash drum, a recycle stream was then purged up to 0.1% for all flowsheets (see section A4.2 of the supplementary material for the sensitivity on recycle fraction). In line with the work of Cui *et al.*, the small purge of 0.1% was set, which aims to minimize the CO₂ emission for the green methanol production.⁶⁶ As observed from Cui *et al.* using a larger purge ratio can result in lower flow rate of the recycle stream as well as a smaller reactor size but a higher CO₂ loss. It was also observed from Cui *et al.* that a value lower than 0.1% may cause convergence problem.⁶⁶ For the syngas (co-electrolysis-based system), the purge stream after methanol separation and recycle was set to 1.3%.

Table 3: Adiabatic plug-flow reactor (s) operating conditions

Parameter	Value	Unit
Tube diameter	3-5	m
Tube length	3-12	m
Reactor inlet pressure	74-75.7	bar
Catalyst particle density	1775	kg/m ³
Bed porosity	0.5	-
GHSV	4000-7300	h ⁻¹

355 2.2.1. Reaction kinetics

356 Industrially, methanol is synthesized from syngas following the three main equilibrium reactions as
 357 expressed by equations 3-5 over an industrial Cu/ZnO/Al₂O₃ catalyst. However, it has been recently
 358 agreed and demonstrated that methanol can also be produced from a feed with pure CO₂/H₂ i.e., via equation
 359 3 only even though the actual reaction mechanism and carbon source for methanol remains an active subject
 360 of debate.¹⁰⁻¹³

364 Following Le'Chaterliers principle, higher methanol yields are favoured at lower temperatures and higher
 365 pressures. However, for the reason of enhancing kinetics, temperatures in the range of temperature 200–
 366 300 °C are used as well as high pressure ranges of 50-100 bar over the commercial Cu/ZnO/Al₂O₃ catalyst.
 367 The reverse water gas shift reaction (equation 4) is the only endothermic reaction in the three main reactions
 368 and therefore gets promoted as temperature increases. This reaction increases the amount of water generated
 369 in the case when pure CO₂/H₂ is the main feed. This lowers the selectivity to methanol and the catalyst
 370 activity. As a result, significant research efforts are devoted to the CO₂ hydrogenation to methanol process,
 371 mostly to improve the catalyst conversion and selectivity.¹⁴⁻¹⁵ However, the commercial Cu/ZnO/Al₂O₃-
 372 based catalyst is likely to remain the best possible for some time due to its ability to achieve highest yield,
 373 its low costs, and high stability.¹⁶ Ruland et al. established, through dynamic experimental conditions
 374 relevant to power-to-methanol (PtMeOH), that the industrial Cu/ZnO/Al₂O₃ is highly stable for conditions
 375 of chemical energy storage with hydrogen produced from fluctuating renewable energy sources, indicating
 376 its relevance for application in PtMeOH.¹⁶ Besides the challenges of optimizing the catalyst beyond what
 377 the commercially available catalyst can achieve to promote CO₂/H₂ to methanol, this reaction is attractive
 378 from an environmental perspective in that a significant quantity of CO₂ can be recycled, and in addition it
 379 is less exothermic, thus rendering ease of heat management in the reactor, and fewer by-products formation.
 380 For these reasons and following the most recent kinetic analysis such as in the work of Nestler et al,
 381 Slotboom et al., and de Oliveira Campos et al., who deduced that the role of CO hydrogenation to methanol
 382 is negligible at high CO₂/CO feed ratio, in this work and only reactions 3 and 4 are considered in the
 383 modelling of the methanol synthesis.⁶⁷⁻⁶⁹

384 The kinetic model used in this study was presented in the work of Van-Dal & Bouallou.⁶⁴ which originated
 385 initially from the model of Bussche and Froment.^{63, 65} The model assumes methanol production from CO₂
 386 hydrogenation (i.e., equation 2) in the presence of RWGS as a competing reaction (equation 4) and absence

387 of diffusional limitations. Thus, the effectiveness factor equals 1. The kinetic model is based on Langmuir
388 Hinshelwood Hougen-Watson (LHHW) kinetic model formulation and is expressed by equations 6 and 7.

$$389 \quad r_{CH_3OH} = \frac{k_1 P_{CO_2} P_{H_2} - k_6 P_{H_2O} P_{CH_3OH} P_{H_2}^{-2}}{\left(1 + k_2 P_{H_2O} P_{H_2}^{-1} + k_3 P_{H_2}^{0.5} + k_4 P_{H_2O}\right)^3} \left[\frac{kmol}{kg_{cat}s} \right] \quad (6)$$

$$390 \quad r_{RWGS} = \frac{k_5 P_{CO_2} - k_7 P_{H_2O} P_{CO} P_{H_2}^{-1}}{1 + k_2 P_{H_2O} P_{H_2}^{-1} + k_3 P_{H_2}^{0.5} + k_4 P_{H_2O}} \left[\frac{kmol}{kg_{cat}s} \right] \quad (7)$$

391 Where k_i were calculated for implementation in ASPEN PLUS V11® using the equation 8 and these are
392 tabulated in Table 4 below.

$$393 \quad \ln k_i = A_i + \frac{B_i}{T} \quad (8)$$

394 Table 5 presents the main parameters of the distillation column which was modelled as RadFrac in ASPEN
395 PLUS V11®.

396 All flowsheets used the same conditions, except only the distillation (DC) in flowsheet 2 in which the
397 boilup ratio was set to 0.9 (lower) to ensure the methanol purity remains above 99wt%. NRTL-RK was
398 selected as a property method to model the distillation column and its feed (with pressure ≤ 1.1 bar).

399

400 Table 4: Kinetic parameters rearranged for implementation in ASPEN PLUS V11® as a LHHW
401 model.^{54,57}

Kinetic parameters	Ai	Bi
k_1	-29.87	4811.2
k_2	8.147	0
k_3	-6.452	2068.4
k_4	-34.95	14928.9
k_5	4.804	-11797.5

Reflux ratio	1.5-1.62	mole
Boilup ratio	0.9- 1.5	mole
Feeding temperature	80	°C
Operating pressure	1.1	bar

404

405 Validation of the kinetic model is presented in the supplementary material section A2. The typical catalyst
406 pellets of 6mm×4mm was packed in the catalyst bed and Ergun equation was used for pressure drop
407 calculation through the catalyst bed. Following process engineering principles, the reactors were sized at

408 constant total reactor(s) volume. A hold-up time of 5 minutes was used in sizing the separators, and the
409 compressor curves were used to model the compressors. Valves were modelled taking into consideration
410 the typical efficiency relations and pressure drops. Thus, in modelling the different systems, the following
411 summary of assumptions were made:

- 412 • An adiabatic fixed-bed tubular reactor has been used to convert CO₂ and H₂ into methanol. The
413 overall CO₂, H₂O or H₂ feed is kept constant as in Table 1.
- 414 • The kinetics model and its parameters are kept constant. Where there are multiple reactors, the total
415 reactor volume of all the reactors combined is kept constant similar to base case flowsheet 1 with
416 one reactor as shown in the Supplementary Material section A3, Figure S3 and Section A5, Table
417 S10. This keeps constant the total amount of catalyst used in all flowsheets, which is paramount
418 for cost effective comparison.
- 419 • The reactor feed temperature is selected in the optimal temperature range (210<T_{in}<240) to
420 optimise the temperature profile and conversion in the reactor.⁶² Refer to the section A4
421 (sensitivity-based optimisation) of the Supplementary Material.
- 422 • The by-products are negligible, and thus the produced materials in the reactor are methanol, CO,
423 and water.
- 424 • Solar PV is used as a source of electricity. In the process, the water is used for cooling.
- 425 • Catalyst deactivation is negligible.
- 426 • The temperature of any flow or equipment is not considered lower than 20 °C, so that there is no
427 need for a refrigerant cycle.
- 428 • The operating conditions have been selected with respect to the limitations of the industrial
429 equipment and considering the outcomes of the design sensitivity analysis in section A4 of the
430 supplementary material.
- 431 • In the hydrogen stream entering the process, 1.2 mol percent of water are considered.

432 2.2.2 System Configurations

433 It is important to highlight all flowsheet comprises a recycle loop, and the SOEC flowsheet was fixed for
434 better comparison. Flowsheet 1 to 6B are shown in the supplementary material section A3 along with their
435 brief description. To be concise, in this section, only the finally selected flowsheet 7, 7B and flowsheet 8
436 are shown as these will be discussed in more details in the subsequent sections. Table 6 gives the description
437 of the different flowsheets. The selection follows from the comparison with flowsheet 1 to 6B as described
438 in the results section 3. Flowsheet 7 illustrated in Figure 3 includes two reactors connected in parallel
439 followed by intermediate separation of methanol and series connection with the third reactor and thereafter,
440 recovery of methanol from the recycle using two separators and a further separation of residual gases at

441 low pressure before the distillation column from which the final methanol product flows. Flowsheet 7B
442 illustrated in Figure 4 has almost similar components as flowsheet 7 but the difference is that all reactors
443 are connected in series. Flowsheet 8 illustrated in Figure 5 has three reactors connected in series, but the
444 flowsheet is simplified series connection version of flowsheet 7B.

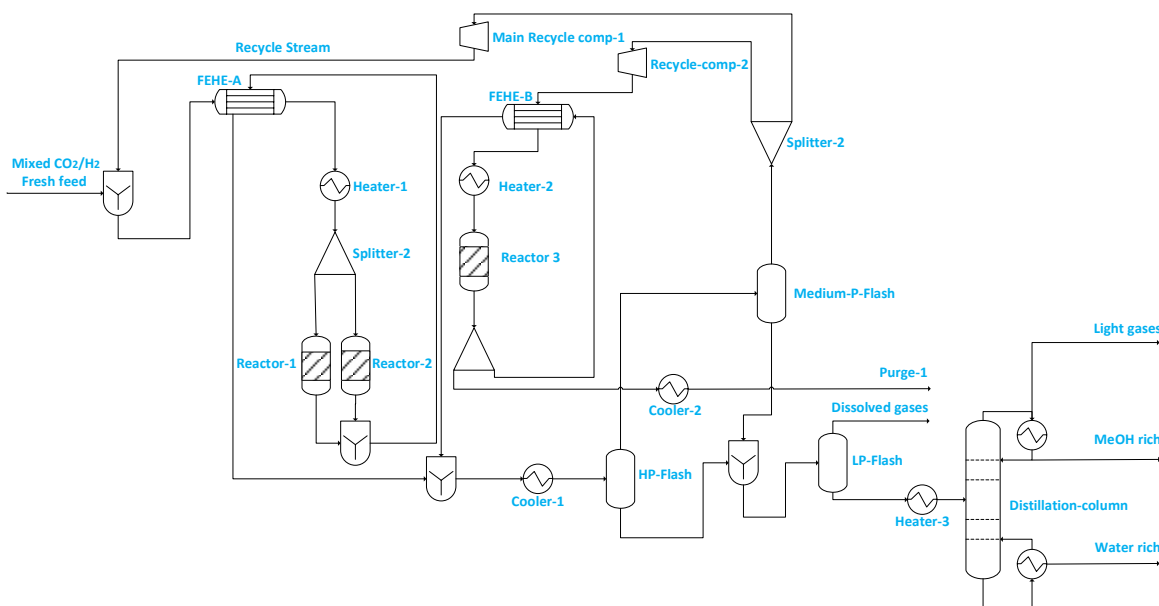

445 Table 6: Description of different flowsheets, their advantages, and limitations.

Process configuration	Description	Advantages	Limitations
Flowsheet 1	This is the base configuration with a single stage adiabatic reactor.	<ul style="list-style-type: none"> • Simple configuration. • Less equipment and thus capital investment. • Simple start-up process. 	<ul style="list-style-type: none"> • Large recycle stream is required for this process. • Low single pass conversion. • More valuable hydrogen purged.
Flowsheet 2	Single stage reactor, with stripper column mounted before the reactor to enhance condensation and separation of methanol from CO ₂ and remove water from the wet hydrogen feed.	<ul style="list-style-type: none"> • Help to prevent catalyst deactivation from wet hydrogen. • Enhances the separation of dissolved gases from the methanol/water mixture. 	<ul style="list-style-type: none"> • Large recycle stream is required for this process. • Low single pass conversion. • More valuable hydrogen purged.
Flowsheet 3	Comprises two adiabatic reactors in series and with intermediate cooling and separation of methanol and water at 45 bar and 35°C. The other feature of flowsheet 3 is the addition of compressor to the feed of the second reactor to raise the operating pressure of the second reactor to the same pressure as the first reactor in the scheme.	<ul style="list-style-type: none"> • Optimises the pressure to the second reactor and the overall pressure profile to enhance methanol production on the second reactor. • Enhances the conversion of the unconverted gases from the first stage. • Reduces the recycle stream. 	<ul style="list-style-type: none"> • Increase number of equipment means more capital investment. • Repeated heating and cooling.
Flowsheet 4	It has two reactors in series but with a wash column which uses C ₃ H ₈ O ₃ as a solvent mounted in the position after the reactor followed by separation and two distillation columns in which the first is used for solvent recovery while the second distillation column is used for methanol purification.	<ul style="list-style-type: none"> • This design enhances the driving force of the reaction by eliminating as much as possible the water and methanol from the unconverted gases. • Enhances the conversion of the unconverted gases from the first stage. • Reduces the recycle and compression work. 	<ul style="list-style-type: none"> • Increase number of equipment means more capital investment. • Increased pressure drop with more reactors, and slightly increased compression. • Complexity and additional solvent recovery requirements. • Repeated heating and cooling.
Flowsheet 5	Closely resembles flowsheet 3 with two reactors in series but with a change in operation of the intermediate separator which is operated at pressure equal to the reactor pressure to avoid the compression of the feed to the second reactor which comprises unconverted gases and some fraction of methanol.	<ul style="list-style-type: none"> • Reduces compression work and recycle. • Enhances the conversion of the unconverted gases from the first stage. 	<ul style="list-style-type: none"> • Increase number of equipment means more capital investment. • Increased pressure drop with more reactors, and slightly increased compression.
Flowsheet 6A	Has two reactors connected in parallel. It also has long recycle to both reactors and therefore a feed (comprising fresh feed and recycle) split at 50% to both reactors.	<ul style="list-style-type: none"> • Increases the residence time in each reactor and thus aims at enhancing the conversion. • Reduces the number of intermediate separators. • Reduces repeated heating and cooling. 	<ul style="list-style-type: none"> • High recycle flowrate. • High compression requirements.
Flowsheet 6B	Has two reactors connected in parallel. It has a short recycle in which the fresh feed flow is split to 50% and the portion of the fresh feed to the second reactor in flowsheet 6B is mixed with all the recycle of unconverted gases whereas the portion to the first reactor is kept as fresh feed.	<ul style="list-style-type: none"> • Increases the residence time in first reactor and thus aims at enhancing the conversion. • Reduces the number of intermediate separators. 	<ul style="list-style-type: none"> • High recycle flowrate • Relatively poor overall conversion. • Removes the recycle as a lever for temperature control in the first reactor especially for part-load operation.
Flowsheet 7	Includes two reactors connected in parallel followed by intermediate separation of methanol and series connection with the third reactor and thereafter, recovery of methanol from the recycle using two separators and a further separation of residual gases at low	<ul style="list-style-type: none"> • Increased reactants conversion and flexible loading/operation. • Reduced compression requirements, and hence potentially improved energy efficiency. 	<ul style="list-style-type: none"> • Increase number of equipment means more capital investment. • Increased pressure drop with more reactors, and slightly increased compression requirement.

Process configuration	Description	Advantages	Limitations
Flowsheet 7B	pressure before the distillation column from which the final methanol product flows. Has almost similar components as flowsheet 7 but the difference is that all reactors are connected in series. The feed to the third reactor is taken from the overall recycle stream and compressed further to boost the pressure.	<ul style="list-style-type: none"> Reduced purge stream and hence CO₂ emissions. Increased reactants conversion. Reduced compression requirements, and hence potentially improved energy efficiency. Reduced purge stream and hence CO₂ emissions. 	<ul style="list-style-type: none"> Complex start-up and shutdown with repeated heating and cooling. Increase number of equipment means more capital investment. Increased pressure drop with more reactors, and slightly increased compression requirement. Complex start-up and shutdown with repeated heating and cooling.
Flowsheet 8	Has three reactors connected in series, but the flowsheet is a simplified series connection version of flowsheet 7B. This configuration has no booster compressor for the feed to all downstream reactors except the main recycle compressor feed.	<ul style="list-style-type: none"> Increased reactants conversion. Reduced compression requirements, and hence potentially improved energy efficiency. Reduced purge stream and hence CO₂ emissions. 	<ul style="list-style-type: none"> Increase number of equipment means more capital investment. Increased pressure drop with more reactors, and slightly increased compression requirement. Complex start-up and shutdown with repeated heating and cooling.
Co-electrolysis flowsheet	Has three reactors connected in series, similar to flowsheet 8. The main difference is the upstream steam-electrolysis step which is replaced to co-electrolysis and thus leading to fresh feed to the reactor with syngas instead and increased CO concentration.	<ul style="list-style-type: none"> Existing catalyst optimised for the syngas feed. Co-electrolysis step enhances the energy efficiency of system. Enhanced conversion with the introduction of CO. 	<ul style="list-style-type: none"> Would practically results in the more impurities and difficulties in downstream separation as the existing industrial syngas systems. Selectivity to methanol decreases with increase in CO/CO₂ ratio.
e-RWGS flowsheet.	Has three reactors connected in series, similar to flowsheet 8. The main difference is the upstream steam electrolysis step which is coupled e-RWGS and thus leading to fresh feed to the reactor with syngas instead, and increased CO concentration.	<ul style="list-style-type: none"> Enhanced conversion with introduction of CO. Existing catalyst optimised for the syngas feed. Higher CO/CO₂ ratio leads to higher methanol production. 	<ul style="list-style-type: none"> Would practically results in the more impurities and difficulties in downstream separation as the existing industrial syngas systems. Selectivity to methanol decreases with increase in CO/CO₂ ratio. Required separation of water formed from e-RWGS reactor.

452 cooling. This features a different feed, product-purge arrangement to the third reactor (reactor 3).

453
454 Figure 5: Illustration of Flowsheet 8. This flowsheet features three adiabatic reactors in series with
455 intermediate cooling.

456 2.3 Dynamic reactors system modelling for flexibility analysis

457 Three of the most promising reactor configurations were selected and assessed in comparison for their
458 flexibility analysis. The loads were varied from minimum to maximum (i.e., 40-102%) with consideration

459 of practicality in the design of the equipment such as pumps, compressors (e.g., to prevent surge and
460 stonewall), etc. Dynamic modelling of the methanol synthesis section is conducted using the ASPEN
461 DYNAMICS V11®. The initial state of the different reactor configurations were extracted from steady-
462 state simulations conducted using Aspen Plus by means of pressure driven approach leading to a more
463 realistic model comparable to real plants. The flowsheets after dynamic translations (with all critical control
464 loops) are shown in the supplementary material, section A4.1. The dynamics of the process are highly
465 dependent on the reaction kinetics and modelling approaches.³⁴ For the dynamic simulation, the distillation
466 section is excluded following the findings from Cui et al. that distillation dynamics, which affects the
467 product quality, is easy to manage under variable loads.⁶⁶ For the methanol synthesis, the feed H₂ and CO₂
468 were mixed at stoichiometric ratio of H₂/CO₂ = 3, before being mixed further with the recycle stream.

469 Signal generators were used during the dynamic modelling, to alter the rates of flow change (i.e., load
470 change) for the feed gases. Moreover, tuned proportional–integral (PI) controllers were used for dynamic
471 operation. The proportional and integral gains were tuned based on the Ziegler-Nichols and Tyreus-Luyben
472 tuning rules by using the automatic controller tuning in ASPEN DYNAMICS V11®. Details of the tuned
473 controllers are shown in the supplementary material. The systems are evaluated considering the KPIs such
474 as energy efficiency, flowrate of the feed streams (i.e., load change), reactor conversion, heat duties and
475 power of the compressors. The hydrogen produced from the renewable electricity and methanol represents
476 the major power input and output, respectively.

477 2.4 Technical performance indicators

478 The mass and energy balance of the process configurations were calculated. The selected indicators to
479 evaluate the studied processes including the overall CO₂ conversion, energy efficiency, production rate, and
480 load change are used as criteria for comparisons. The energy efficiency expressions of the SOEC system,
481 and the overall system defined below, follows from the work of Lonis et al. and Cui et al.^{59–60, 66} For the
482 SOEC unit operating to produce hydrogen or syngas as the key product, equation 9 describe the expression
483 for the efficiency the water electrolysis section.

$$484 \quad \% \eta_{SOEC, product} = \frac{\dot{m}_{product} \times LHV_{product}}{P_{SOEC} + P_{BOP,SOEC}} \quad (9)$$

485 Where $\dot{m}_{product}$ refers to the mass flowrate of hydrogen or syngas (for co-electrolysis), $LHV_{product}$ refers to
486 the lower heating value of hydrogen or syngas, P_{SOEC} refers to the electric power of the SOEC while
487 $P_{BOP,SOEC}$ is the power of the SOEC auxiliaries. Single pass conversion of carbon is expressed by equation
488 10. The CO is considered in the calculation of single pass conversion since the feed to the reactor contains
489 CO introduced by recycle although the overall system boundary feed to the process doesn't contain CO but

only CO₂ and H₂O. The efficiency of the integrated SOEC and the methanol synthesis i.e., the PtMeOH efficiency can be described using equation 11.

$$\% \eta_{C, conversion} = \frac{(CO_{2, in} + CO_{in}) - (CO_{2, out} + CO_{out})}{(CO_{2, in} + CO_{in})} \quad (10)$$

$$\% \eta_{PtMeOH} = \frac{\dot{m}_{MeOH} \times LHV_{MeOH}}{P_{SOEC} + P_{BOP, SOEC} + E_{MSS} + P_{BOP, MSS}} \quad (11)$$

Where E_{MSS} refers to the heat energy requirements in the methanol synthesis unit (MSS) i.e., for preheating the feed to the reactor and distillation column, and for reboiler in the distillation. The \dot{m}_{MeOH} (kg/h) is the mass flow rate of the streams, LHV is the lower heating value for the gases, and P represents the heat duty of the heat exchangers or the power inputs for the recycle compressor and pumps. Furthermore, heat integration is also considered for all the most promising flowsheets and thus the composite curves and exchanger designs are investigated. Heat integration eliminates/reduces external heat requirements in the methanol synthesis and distillation section (i.e., yield to $E_{MSS} \approx 0$). A brief analysis of the impact of heat integration on the three selected flowsheets (flowsheet 7, 7B and 8) is presented in section A4.3 of the Supplementary material.

3. RESULTS AND DISCUSSION

3.1 Electrolyser performance: steam vs co-electrolysis

Table 7 summarises the energy balance pertaining the heating and cooling within the SOEC system. High temperature SOEC) has an advantage in terms of having higher energy efficiency. This is because this technology utilises both heat and electricity. In general, the higher the temperature the lower the electricity demand. On the other hand, increasing the temperature reduces the overvoltage losses i.e., the ohmic losses. Therefore, the SOEC exhausts (anode and cathode) are used to preheat and superheat the feed streams containing recirculated oxygen sweep gas and demineralized water.

Table 7: Energy balance in the SOEC section under steam electrolysis.

Heating process	Heat (kW)	T _{in} (°C)	T _{out} (°C)	Cooling process	Heat (kW)	T _{in} (°C)	T _{out} (°C)
Sweep air PH by heat recovery (FEHE6)	116	248	650	Anode exhaust 1st cooling (FEHE6)	-113	850	831
Sweep air SH by external source (Heater3)	61	650	850	Anode exhaust 2 nd cooling (FEHE4)	-1273	831	619
Water PH and VAP external heat (Heater1)	21602	28	180	Anode exhaust 3 rd cooling (FEHE2)	-137	619	595
Water SH by heat recovery (FEHE1)	2422	180	332	Anode exhaust 4 th cooling (ANOD-COOL)	-2587	595	130
Water SH by heat recovery (FEHE2)	137	332	340	Cathode exhaust 1 st cooling (FEHE5)	2110	850	707
Water SH by heat recovery (FEHE3)	2755	340	505	Cathode exhaust 2 nd cooling (FEHE3)	-2755	707	515
Steam SH by heat recovery (FEHE4)	1273	505	579	Cathode exhaust 3 rd cooling (FEHE1)	-2422	515	342
Water SH by heat recovery (FEHE5)	2111	579	697	Cathode exhaust 1 st cooling (CAT-COOL)	-9023	342	35
Steam SH by external heat (Heater 2)	2835	714	850				

SH=super heat, VAP=vaporisation, PH=preheating

513 Additional external heat source is still required to preheat and vaporise demineralized water, and further
 514 raise the temperature of the demineralized steam and sweep gas to the SOEC operating temperature (850
 515 °C). Table 8 summarises the performance of the steam and co-electrolyser considering the power
 516 consumption and energy efficiency. The steam electrolysis-based SOEC required to produce about 1213
 517 kmol/h of hydrogen under the operating conditions stipulated in Table 2, a corresponding electrical power
 518 of approximately 109 MW is required. Since the electrolyser is operated at thermoneutral voltage, the
 519 efficiency is high due to negligible overpotential losses compared to endothermic operation.⁵⁵ The steam-
 520 based SOEC system efficiency value of $\eta_{\text{soec,system}} = 74.5\% - 78.2\%$ obtained in this work is comparable to
 521 values that have been reported in literature for the SOEC efficiency values^{52-53, 55-56} at thermoneutral voltage
 522 such as the value ($\eta_{\text{soec,system}} = 83\%$) which was presented in the work of Lonis et al. who used the definition
 523 of energy efficiency similar to equation 9 above, even though the model for SOEC was fairly simplified in
 524 this work.⁶⁰ The slight under-estimation of efficiency in this work is perhaps due to the differences in model
 525 formulation. However, the results are very comparable to what literature reports for SOEC energy
 526 efficiency at thermoneutral voltage^{52-53, 55-56} and thus giving confidence about the relevance of model
 527 formulation assumptions in this work. On the other hand, the co-electrolysis based SOEC efficiency
 528 considering the BOP energy consumption was found to be around $\eta_{\text{soec,system}} = 76 - 79\%$ and comparable to
 529 literature.^{32, 55} The power consumption in co-electrolysis mode is however higher than that in the steam
 530 based SOEC mode and this trend is similar to that found by Patcharavorachot et al.⁵⁰ This is because in co-
 531 electrolysis mode, both H₂O and CO₂ conversion reactions consume electrical power.⁵⁰

532 Table 8: Performance of the electrolyser system for steam electrolysis and co-electrolysis

Parameter/index	Units	Steam-electrolysis	Co-electrolysis
		Value	Value
LHV (H ₂ or CO+H ₂)	MJ/kg	120	25
P _{soec}	MW	84	107
P _{soec,BOP}	MW	25	27
$\eta_{\text{soec,system}}$	%	74.5	76.2
$\eta_{\text{soec,system,R}}$	%	78.2	79.2

533
 534 However, for the co-electrolysis-based mode, a slightly higher (1.7% more than water-electrolysis mode)
 535 overall SOEC system energy efficiency was obtained for the same ratio. This is mainly due to reduced feed
 536 steam requirements in co-electrolysis mode, as part of the steam is produced from CO₂ to CO reaction (i.e.,
 537 RWGS). It is also critical to highlight that the hot streams from the SOEC have been used only for the
 538 heating of the cold streams in the SOEC section to avoid complications of the process and to better assess
 539 the influence of the configured methanol synthesis section on the overall energy efficiency of the process.
 540 This renders the two system thermally independent, which is advantageous when variable renewable

541 electricity is used in PtMeOH, provided this is achieved at minimal possible cost. This allows for some
542 degree of flexible part-load operation for each section with reduced regulation or operation issues.

543 As also highlighted by Chen and Yang et al., integration of heat between two or more subsystems should
544 be minimized unless otherwise necessary, and optimal integration (also reducing heat curtailments) within
545 a subsystem should be maximised.³¹ For the final heating of the steam via heater 3, an external source is
546 required (e.g. electricity) in order to achieve the operating conditions of the SOEC. An alternative would
547 be to operate the electrolyser above thermoneutral point and thus use the surplus heat from overpotentials,
548 but this is not considered in this study as it adversely promotes cell degradation. External electrical heat
549 requirements for the SOEC section ($\approx 24\%$ of the total electrolysis power) is needed to generate superheated
550 steam and heat the sweep gas to the SOEC temperature. The sweep gas must first be compressed and heated
551 to the SOEC temperature.

552 **3.2 Methanol Production Rate, Energy Efficiency, Overall and Single-pass CO₂ and H₂** 553 **Conversion**

554 Comparison of the process flowsheet configurations based on methanol production rate, energy efficiency,
555 carbon conversion and H₂ conversions are shown in Figure 6, Table 9 and 10. The overall CO₂ conversion
556 is calculated considering a recycling system in all configurations. Comparison of the methanol production
557 rate shows that three reactors, gives higher methanol production rate. The highest methanol production rate
558 is found for flowsheet 7B which comprises of three reactors in series with intermediate cooling and
559 separation. Comparison of the process flowsheets (see Figure 6) depicts that configuration expressed as
560 flowsheet 5 has a slightly higher energy efficiency. Flowsheet 7B has a similar overall CO₂ and H₂
561 conversion and energy efficiency as flowsheet 7 and flowsheet 8. However, the flowsheet 7B differs slightly
562 (about 1% less) in terms of the energy efficiency compared to flowsheet 5. Table 9 shows the single pass
563 CO₂ conversion of each reactor per flowsheet configuration. Since the process configuration of flowsheet
564 1 and 2 follows from the work of Van-Dal & Bouallou and Kiss et al. the single pass CO₂ conversion from
565 this work are comparable to those of Van-Dal & Bouallou and Kiss et al. for flowsheet 1 and 2,
566 respectively.^{54,58, 63} The reason the flowsheets 1 and 2 were re-modelled in this work was to ensure fair
567 comparison using similar scale and process conditions since the original work of Van-Dal and Bouallou
568 and Kiss et al. used distinct conditions and/or target production capacities and kinetics.^{61, 64, 70} Even if the
569 capacities were to be similar, different operating conditions will yield different performance. Single pass
570 conversion in series reactors with intermediate cooling shows an increasing trend as reactor stages increase.
571 This is so as the removal of water and methanol via intermediate cooling and separation increases the
572 driving force of the CO₂ conversion reaction and thus enhances CO₂ conversion. Although flowsheet 2 can
573 produce a high methanol comparable to flowsheet 7, 7B and 8, it has a slightly lower energy efficiency.

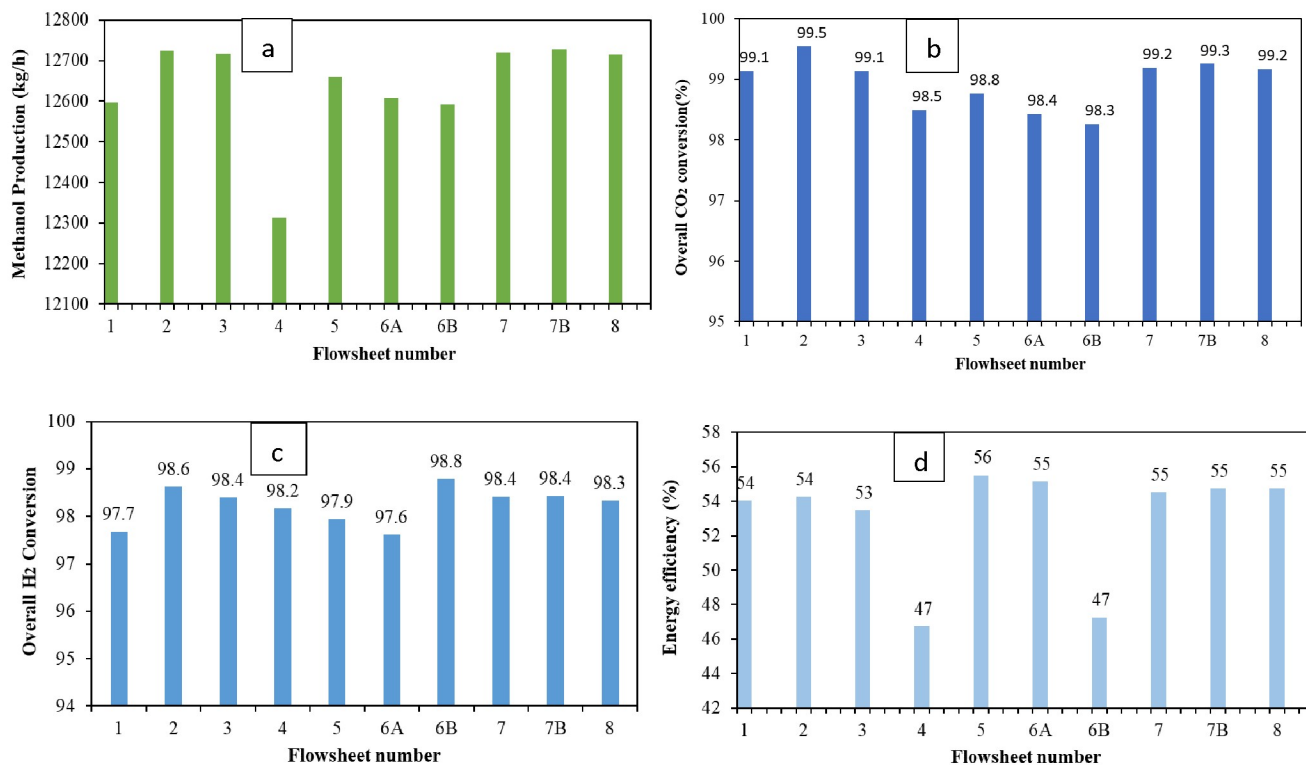

Figure 6: Performance of the different flowsheet considered in this paper: (a) methanol production. (b) overall CO₂ conversion. (c) Overall H₂ conversion. (d) Overall energy efficiency of the process.

Table 9: Single pass carbon conversions of each reactor in the evaluated process configurations.

Reactor (R)	Flowsheet number									
	1	2	3	4	5	6A	6B	7	7B	8
	% CO ₂ Conversion in each reactor in the flowsheet									
R1	39.1	17.8	39.7	39.0	40.4	42.0	47.4	51.5	32.8	30.3
R2	-	-	53.6	53.9	55.8	42.0	10.1	51.5	42.8	40.3
R3	-	-	-	-	-	-	-	34.5	50.2	46.6

Table 10: Single pass H₂ conversions of each reactor in the evaluated process configurations.

Reactor (R)	H ₂ % conversion per flowsheet number per reactor									
	1	2	3	4	5	6A	6B	7	7B	8
R1	9.3	18.6	8.6	9.2	9.2	9.2	8.1	7.0	11.1	11.2
R2	-	-	6.7	7.0	6.5	9.2	4.3	7.0	9.6	10.0
R3	-	-	-	-	-	-	-	10.2	7.6	7.5

575 Despite effort to recover as much methanol in flowsheet 4 with additional separation via solvent wash
 576 column, the overall methanol production and energy efficiency is not improved for this process. This is
 577 because thermodynamically limits on recoverable methanol in a given stream. This process may also
 578 introduce losses of valuable reactants that may otherwise be recycled and reconverted. For parallel reactors
 579 having a short recycle stream, similar to configuration in Flowsheet 6B, slightly decreases the overall
 580 methanol production rate and CO₂ conversion. The short recycle also results in large recycle stream and
 581 hence increased recycle compressor duty. This decreases the energy efficiency and hence flowsheet 6B has
 582 low energy efficiency as indicated in Figure 6d. When these parallel reactors are designed with a long
 583 recycle (flowsheet 6A) and equally divided feed each reactor has a single pass conversion slightly higher
 584 than flowsheet 1 & flowsheet 2 which is expected because a smaller mole flowrate of the reactants is fed
 585 for comparable catalyst mass inside these reactors, thus resulting into higher residence time and hence
 586 increased carbon conversion.

587 Table 11: Comparison of the energy efficiency obtained from this study and those found in literature.

588
 589 The trend of conversion with changes in flowrate is also observable when reactors are staged in series with
 590 intermediate cooling. The rapid increase in the conversion of R3 corresponding to Flowsheet 7B is a result
 591 of significant reduction in its feed flow-rate since the series staging of the reactors converts more of the
 592 reactants (overall, each reactor in the earlier stages receive higher flows) and the subsequent intermediate
 593 segregation of methanol and water which increase the driving force on reactor R3. In addition, the analysed
 594 process conversion is higher due to absence of impurities in the feed. The results are comparable to the
 595 findings of Basonde & Urakawa, who experimentally demonstrated the similar single pass CO₂ conversion
 596 using 10:1 H₂/CO₂ feed.⁷³ The performance that would be achieved with 3.333 times more hydrogen
 597 (expensive to make from electrolysis) than the stoichiometric ratio in the feed is the same as having the
 598 configurations as discussed with the H₂/CO₂ of 3:1 in the overall feed. Thus, the reactor configuration
 599 strongly influences the conversion of CO₂ to methanol.

600 Hydrogen storage is another key goal of the PtMeOH process. In this regard, the storage of hydrogen is
 601 assessed in terms of the amount of hydrogen that is converted to methanol in the process. Viewed from the

602 overall process-based hydrogen conversion as depicted in Figure 6, methanol production using flowsheet
603 6B with short recycle had a higher overall H₂ conversion. This is achieved without application of hydrogen
604 gas recovery, e.g. membranes, which are often applied industrially to increase the overall conversion of
605 hydrogen. The use of membrane was not considered in this paper due to its potential to increase the methanol
606 production cost. Table 10 shows the single pass conversion of hydrogen to methanol. The single pass
607 conversions of hydrogen are lower than the CO₂ single pass conversions since hydrogen is always in excess
608 in the feed of the reactor due to a significant amount of it in the recycle.

609 Figure 6 also plots the energy efficiency of the flowsheets. The trend without heat integration shows that
610 flowsheet 5 has the highest energy efficiency followed by flowsheet 7, 7B and 8. However the production
611 rate of flowsheet 5 is slightly lower than those of flowsheet 7, 7B and 8. This is because flowsheet 7, 7B
612 and 8 have the additional reactor which converts more materials and thus have a slightly higher production
613 rate. This shows a trade-off between the energy efficiency and the production rate. As the production rate
614 increases energy efficiency decreases slightly. For flowsheet 5, the intermediate flash drums for separation
615 of methanol and water from unconverted gases are operated at high pressures. This in effect reduces the
616 energy requirements and size of the compressors to the second reactor and recycle. This depicts a trade-off
617 between compression cost and flash drum pressure as observed by Luyben et al.⁹ This implies that caution
618 must be taken to avoid increasing pressure excessively in a way that the contents of unconverted gases and
619 inert in the liquid stream sent to the distillation column increases (thus reducing the quality of the product)
620 or significantly reducing the pressure and thus increasing the compression requirements of the recycle
621 compressor. The flowsheet 7, 7B and 8 have the same energy efficiency (see Table 11). Thus, this indicates
622 a trade-off, between production rate and energy requirements which has been articulated by several other
623 authors.^{22, 56} However, looking at the temperature profile at the exit of the reactor in flowsheet 7, 7B, 8
624 opportunities for heat integration exist and could improve the energy efficiency of the process. Mechanical
625 work and process heating (excluding the integrated heating) in this work are powered by electricity only.
626 Energy efficiencies are still low, and this indicates the need to perform heat integration analysis and heat
627 exchanger network design which is summarily performed and discussed in section A4.3 of the
628 supplementary material. Before performing heat integration, sensitivity-based optimisation of the reactor
629 section of the flowsheets is investigated for flowsheet 7, 7B and 8 to determine the optimal operating
630 conditions associated. The results of the design sensitivity are shown in section A4.2 of the supplementary
631 material. Sensitivity on critical parameters such as the recycle ratio, fresh feed partitioning, feed
632 temperature reactor, separator pressure and temperature were performed. The findings show that fresh feed
633 partitioning does not change the methanol production rate but can influence the control of the hot spot
634 temperature and offer a degree of freedom under dynamic operation. From the heat integration, the series-
635 series configuration showed low utility requirements upon optimisation of the heat exchanger network.

636 3.3 Assessment of flexibility of the methanol synthesis section

637 3.3.1 Feed flowrate and product streams

638 Generally, reactor configurations influence the flexibility of the process.³² In this section, both parallel-
639 series and series-series based configuration are assessed. Both series- and parallel-series-based
640 configurations with three reactors are modelled under dynamic conditions by changing the load (feed
641 flowrate). Simultaneous modulation of the CO₂ and H₂ feed is performed to maintain the CO₂:H₂ ratio of
642 1:3 in the feed. In a cascade series-series reactor design (i.e., flowsheet 7B, 8 and syngas-based flowsheet),
643 changes in the conversion and temperature in one stage influences the reaction rate of the next stage. The
644 non-linear relationship of temperature and concentration may render some intermediate load points
645 infeasible, even though the minimum and maximum may be feasible. However, this was found to not be
646 the case for all the four designs considered in the present study. The minimum and maximum loads used in
647 this study are $\beta_{min} = 40\%$ and $\beta_{max} = 105\%$ for flowsheet 7, 7B and 8. While the syngas-based
648 flowsheets had the minimum allowable load-change of 45% of the nominal. Below these β_{min} values, the
649 Aspen Dynamics integrator fails. The part-load refers to 50% of nominal load. In this study, a load ramp
650 (R) of 60% load per hour and a total time on stream of 15 hours were considered. Figure 7 shows effect of
651 load change from full-load to part-load on flowrates of the main feed and product streams. A linear decrease
652 in the flowrate from full-load to part-load occurs during t=1–2.19 h and linear from full-load to part-load
653 increase from t=5–9.51 h is depicted. This is desirable as it promises quick and good response to process
654 variability under intermittent renewable energy. As expected, following the previous study on a single
655 reactor by Cui et al. both the methanol production rate and the purge stream follows the same trend of the
656 load change.⁶⁶

657 All three configurations had the relatively comparable process flexibility; meaning they all
658 achieved/tolerated minimum to full load operation without any violation of path constraints such as
659 maximum allowable temperature in the reactors. However, it took 1.08, 1.16 and 1.19 h to reach the part-
660 load steady state for flowsheets 7, 7B and 8, respectively. To reach the full load steady state from the part-
661 load conditions, it took 1.51, 3.21 and 4.51 h for flowsheet 7, 7B and 8, respectively. Small undershoots
662 and overshoots are observed on the purge stream for all flowsheet at minimum load. Although these
663 flowsheets can handle the load change very well, parallel-series configuration (flowsheet 7) seems to be
664 attractive with the ability to reach steady state faster. For all flowsheets, dual control (split range control)
665 of the recycle split ratio (see flowsheets details on the supplementary material) was necessary to reach low
666 load levels and hence dynamize the methanol synthesis section. In Figure 7B, there is an overshoot in the
667 purge after part-load operation and it took longer than 24 hours for the purge in this flowsheet to stabilise
668 to the initial steady state value. When comparing the CO₂ hydrogenation-based flowsheet to the syngas-

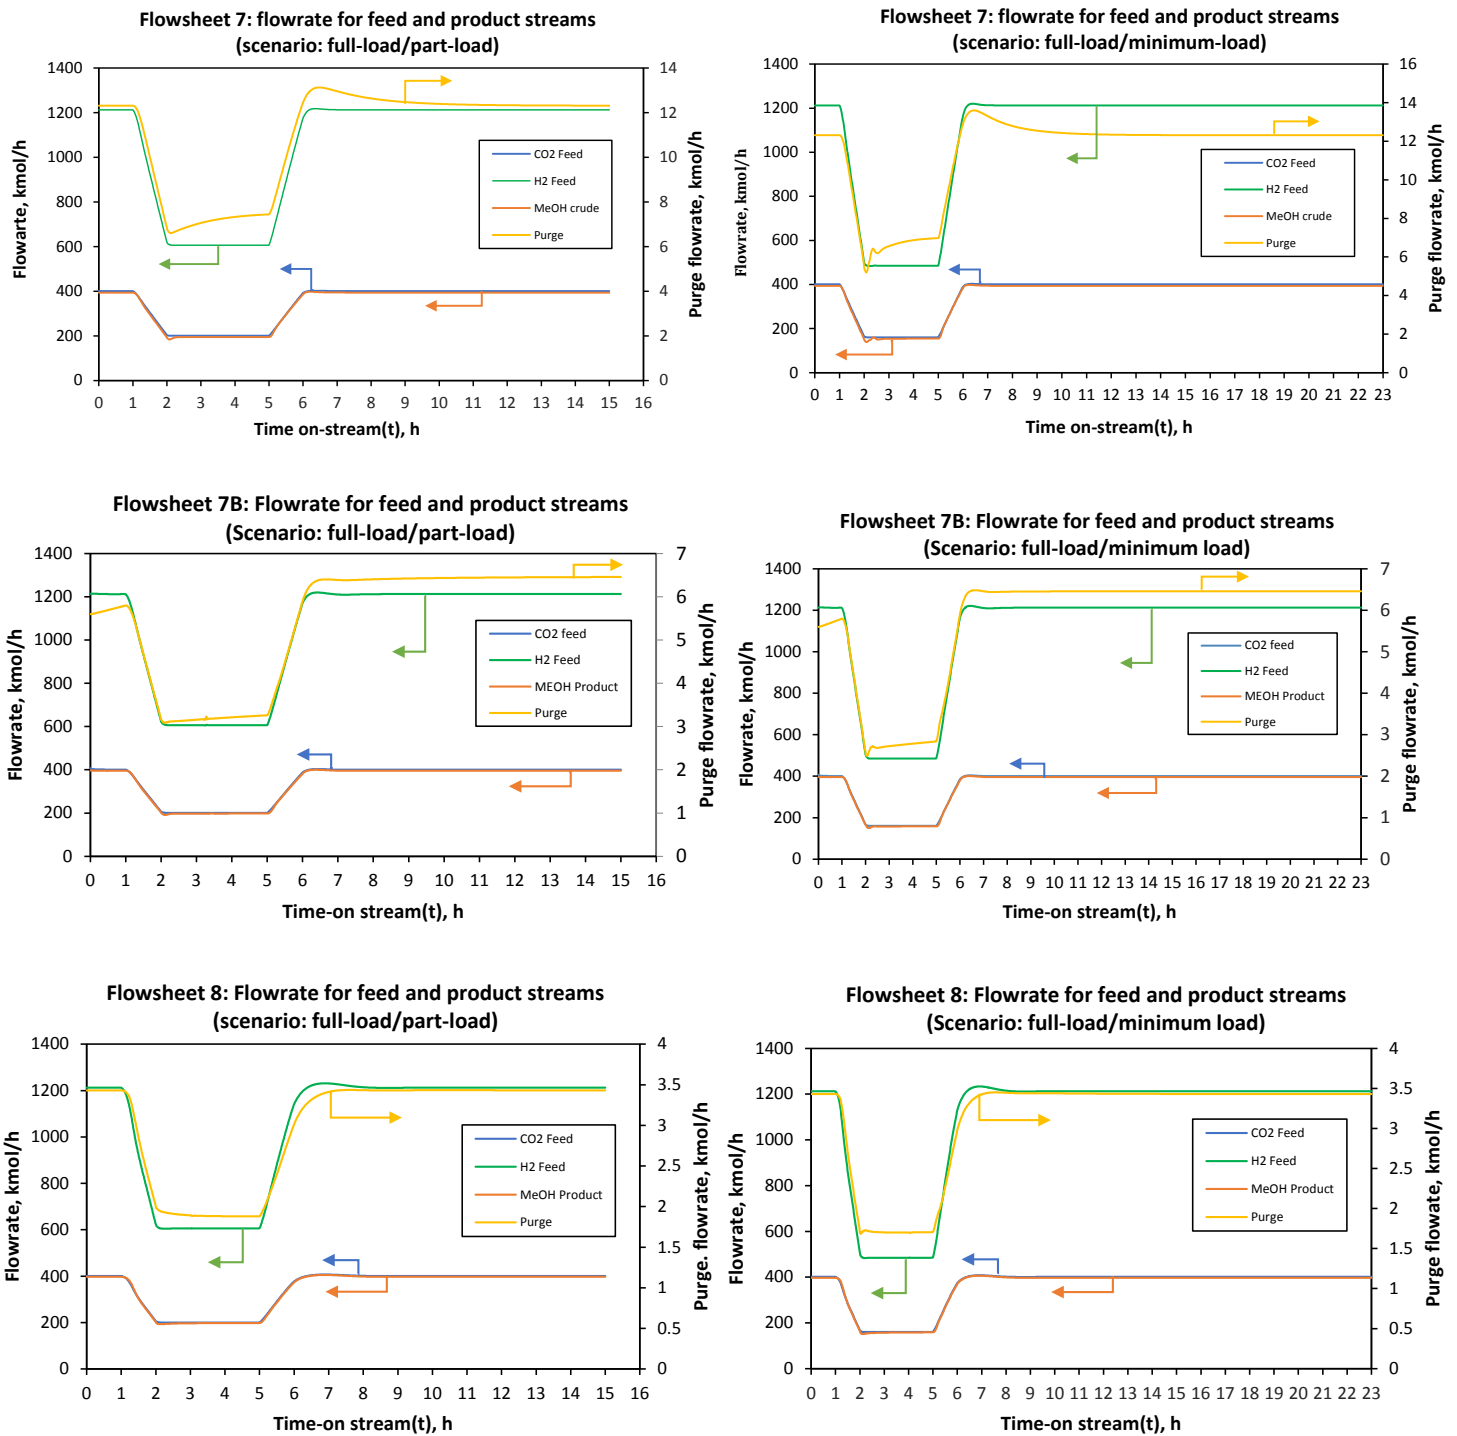

Figure 7: Shows the flowrate of the feed and the product streams when the load was changed from full-load (100%) to part-load (50%) and minimum load (40%). These results are for flowsheet 7, flowsheet 7B and flowsheet 8.

669

670 based flowsheets as depicted by Figure 8, the CO₂ hydrogenation had better load flexibility than the syngas-
 671 based flowsheet, even though the architecture of syngas-based flowsheet is similar to series-series flowsheet
 672 8. However, operation at loads higher than nominal is possible (up to 110% for syngas-based flowsheet).

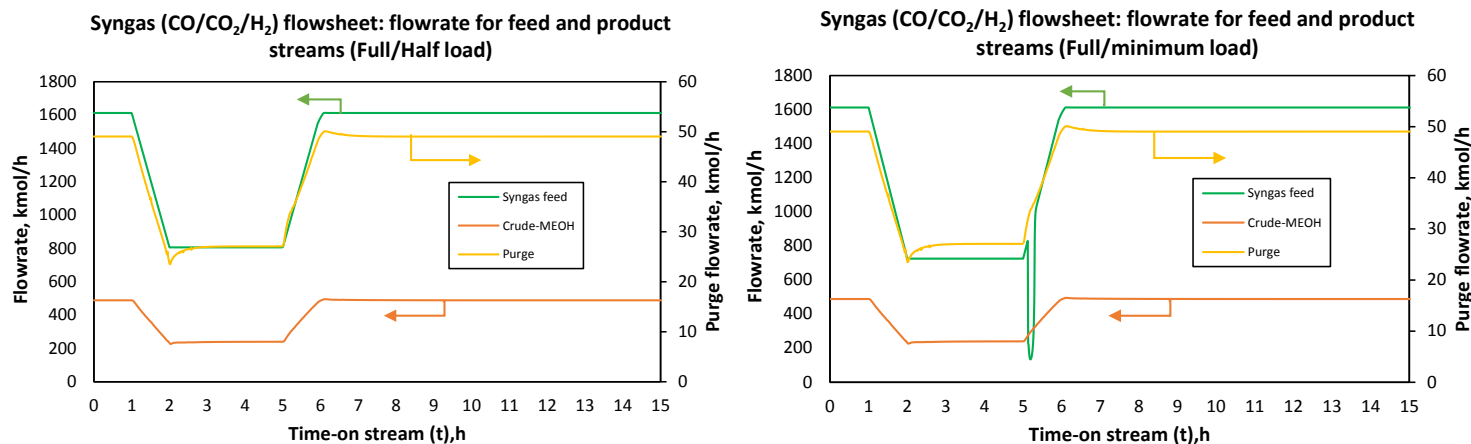

Figure 8: Shows the flowrate of the feed and the product streams when the load was changed from full-load (100%) to part-load (50%) and minimum load (45%) for co-electrolysis derived syngas to methanol.

673 Syngas-based flowsheet was also marred by the instabilities at minimum load, where undershoot were
 674 observed on the purge and syngas-feed when the load was ramped from the full-load to part-load and
 675 minimum loads to full-load. It also takes a while for the recycle splitter to maintain the split ratio and hence
 676 the observed drops in the purge stream. Any flowrate within the defined load range can be reached
 677 successfully, safely and without system shutdown when the control system is properly designed. The
 678 change in the adiabatic reactors exit temperatures with the load change was almost negligible for the CO₂
 679 hydrogenation reaction. This is because as the feed flowrate is increased or decreased, the heat released is
 680 distributed across the reactor at higher feed flow, and the reverse water-gas shift reaction which gets more
 681 promoted at high residence time balances out the heat released at reduced flow. One would expect that with
 682 more methanol production more heat will be released in the reactors, but this is mitigated by these factors.
 683 In addition, the large recycle stream also causes the balancing effect providing the necessary temperature
 684 control and distribution. However, the potential effects of inaccuracies of the steady state kinetic model
 685 used to simulate the dynamic thermal profile must be investigated further. The current results shows that
 686 the storage capacity between the methanol synthesis reactors and the upstream process (electrolysis and
 687 CO₂ capture) can be reduced at-least to allow for operation in the defined load range (40-100%). Lower
 688 part-load are expected to be problematic more especially for the syngas-based process since the increase in
 689 residence time results into higher heat evolution inside the reactors creating possibility of hot-spot
 690 formation. However, the final decision on the design of the feed storage capacity(s) on the upstream of the
 691 first stage reactor will be detected by the economic feasibility of each point. The economics under dynamic
 692 conditions are not considered in this study. Regardless, it is clear from the analysis in this study that
 693 methanol synthesis via adiabatic reactors can operate over an extended load range comparable with
 694 adiabatic reactors for methanation reaction.³²

695 **3.3.2 Composition of the feed**

696 The composition of the feed of the reactor varies with load change as depicted in Figure 9. For the parallel
697 –series and series-series configuration, the CO₂, methanol, H₂O and CO molar content in the feed of all the
698 three reactors decreases with decrease in load; interestingly following the same trend as the load change.

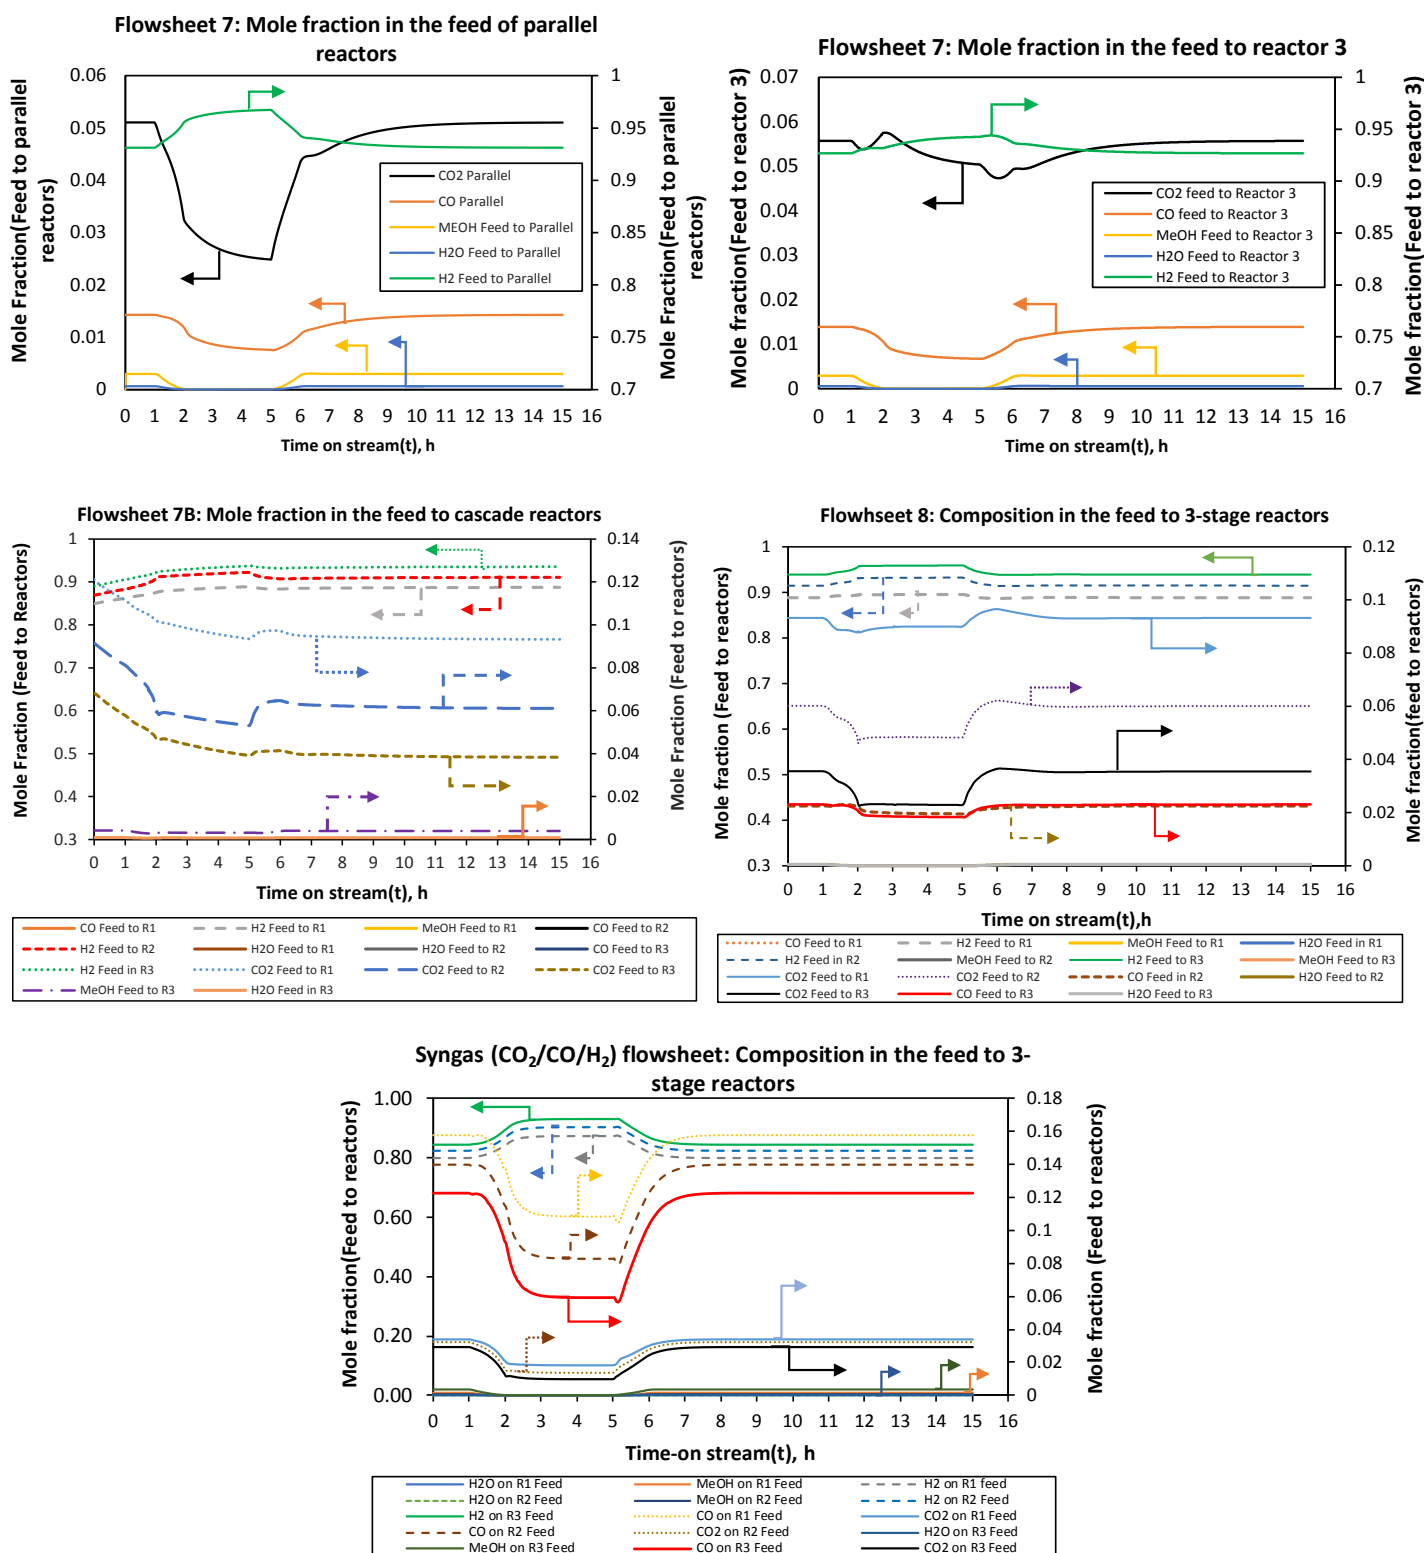

Figure 9: Shows the compositions of the feed streams to the reactors when the load was changed from full (100%) to half-load (50%).

720 However, the H₂ fraction in the reactor feed follow an opposite trend to load change. When load is reduced
721 the H₂ content at all reactor inlet increases for all flowsheets. This is attributed to the fact that much of CO₂
722 gets converted during the load change such that, hydrogen is present in excess due to the recycle. High
723 hydrogen content is seen in the last stage reactor. This is an interesting finding that hydrogen is in excess
724 in the feed of the load flexible reactor during part-load. There is a slightly decreasing trend in the CO₂,
725 methanol, H₂O and CO composition for Reactor 3 in flowsheet 7 and 7B, while flowsheet 8 shows a
726 relatively similar decrease as with other reactors.

727 This shows that in flowsheet 8 the concentration inertia is eliminated across the process which is required
728 to ensure flexible operation. It takes longer hours for the composition to achieve steady state, at-least for
729 flowsheet 7 compared to flowsheet 8 and syngas-based flowsheet, as the load change, more especially for
730 the last stage reactor in flowsheet 7. For flowsheet 8 and syngas-based flowsheet, the compositions need
731 fewer hours to return to normal steady state after the disturbance. The parallel-series configuration
732 (flowsheet 7) had pronounced overshoots and undershoots in the H₂ and CO₂ compositions.

733 **3.3.3 Heat exchanger and compressor duties**

734 Following the analysis of the Figure 10, the duties of the heat exchanger and the power of the compressors
735 follow almost the same linear trend as the load change for all configurations. Considering the compressors
736 duty for flowsheet 7, 7B and 8, there seems to be a similar linear decrease trend in the power of the recycle
737 compressor(s) with changes in load from full (100%) to part-load (50%). For example, the compressor
738 power for flowsheet 8 decreased from 236 kW at full-load to 131 kW at part-load, which is almost a 55%
739 decrease. This can also be attributed to the high conversion at part-load (see Figure 12 for trend on
740 conversion). On the other hand, for all the coolers in the considered systems, there is an increase in the
741 cooling duties. This trend is similar to what Cui et al. observed and attributed to the quality of heat in the
742 exit streams from the reactors, i.e., low grade heat of reactor effluent streams demands more cooling duty
743 at part-load.⁵⁷ This is indeed the main energy loss for the methanol synthesis as has been discussed by other
744 authors.⁵⁷ However, the impact of effective heat integration (that doesn't constraint flexibility but
745 maximises the economics of the process) must be studied. It is expected that this may reduce the cooling
746 requirements/demands for the methanol synthesis section. Again, the thermal inertia for the considered
747 designs seems to be negligible. However, this remains to be confirmed. The heat exchanger duties are high
748 for parallel-series flowsheet 7 compared to the series-series configuration and the lowest exchanger duties
749 are found in the syngas-based configuration, more especially for the heaters. For all configurations no
750 unfeasible heat exchanger duties (e.g., negative duties for the reactor preheaters) were observed.

771

3.3.4 Load dependent energy efficiency

To assess the load dependency of the energy efficiency of the three methanol synthesis configurations, a case without heat integration (no feed effluent heat exchange (FEHE) was simulated) while a case with minimum reactor outlet-feed heat integration (HI) (via hypothetically FEHE) was assumed. The trend depicted in Figure 11 shows a more pronounced decrease in energy efficiency with a decrease in the load for all the flowsheets when the heat integration via feed effluent (without FEHE) is not considered. For flowsheet 7 and 8, when the heat required to raise the temperature of the feed stream(s) to the reactor(s) feed was set to zero (assuming there could be heat integration using FEHE), the energy efficiency shows a very small variation from the full-load to all load levels (maximum, intermediate and minimum).

Figure 11: Shows the energy efficiency of the three configurations when the load was changed from full (105%) to half-load (50%), intermediate load (80%), and minimum load (40%). The ramp rate was kept constant at 60% load per hour.

For flowsheet 7B and 8, the energy efficiency is almost stable at steady state/full load energy efficiency when this minimum heat integration is considered. Although this heat integration is necessary to improve the energy efficiency, in real system it may induce the thermal oscillations due to tight coupling with the reactor. The assumption of a perfect (hypothetical) FEHE per reactor stage shows that enhancement of thermal dynamics is expected to improve the energy efficiency of the PtMeOH system. This will be more necessary and advantageous for the coupled methanol synthesis and upstream (electrolysis) at higher ramping rates since it is expected that the energy efficiency of the electrolysis will increase at low load and hence potentially increasing the overall energy efficiency of the coupled system.

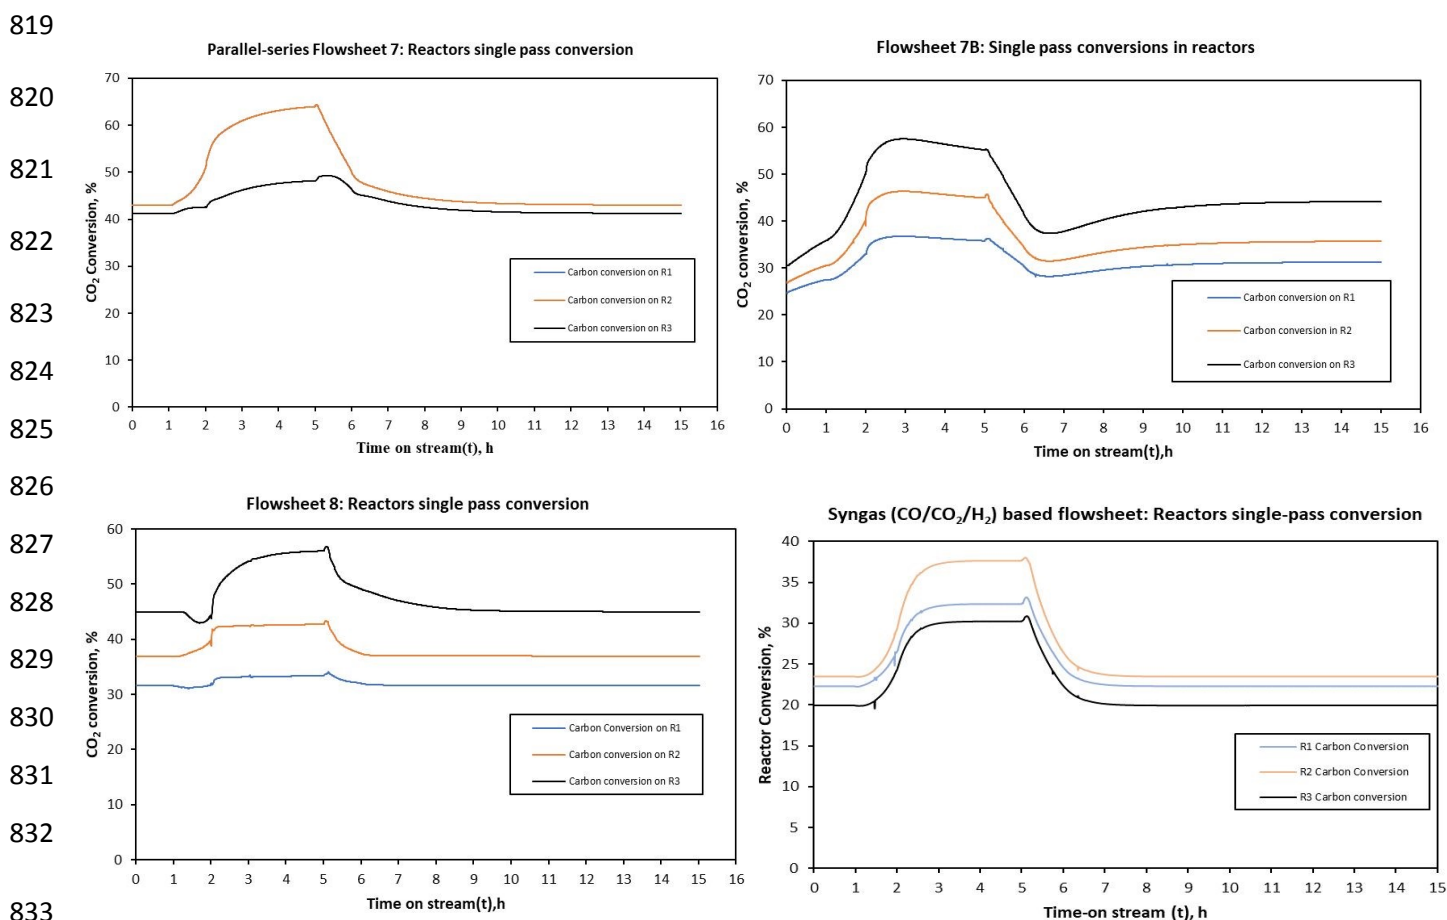

The findings on energy efficiency trend for flowsheets 7 and 8 are similar to the recent finding that for a direct methanol synthesis reactor, dynamic modelling studies suggest that for part-load production capacity the energy efficiency does not decrease significantly as also deduced by Cui et al.⁶⁶ The energy efficiency of the methanol synthesis system in flowsheet 8 is higher than the other flowsheets. This effect is however

809 dampened by the electrolysis and distillation units when the overall integrated steady state simulation was
 810 considered in Figure 6 but it is expected to be more pronounced when effective heat integration is
 811 considered. For the syngas-based route, the load dependent energy efficiency is found to be lower than the
 812 other CO₂ hydrogenation systems, more especially when compared to flowsheet 8. The energy efficiency
 813 fluctuates significantly with decrease in the load. At loads above the nominal, the energy efficiency doesn't
 814 change significantly.

815 3.3.5 Single pass conversion

816 Conversion changes with load change. As illustrated in Figure 12, at part-load, the conversion is higher
 817 than the conversion at full-load for all the configurations. This is expected as the reduction in flowrate
 818 increases the residence time inside the reactor(s) and hence a positive step change in conversion result.

832 Figure 12: Shows the single pass reactor conversion for the three system configurations when the load was changed
 833 from full (105%) to half-load (50%).

835 The increase is slightly higher for parallel-series configuration in the parallel reactors (R1 and R2) due to
 836 their capacity and the fact that each feed to these reactors is further decreased, i.e., split by 50%, and thus

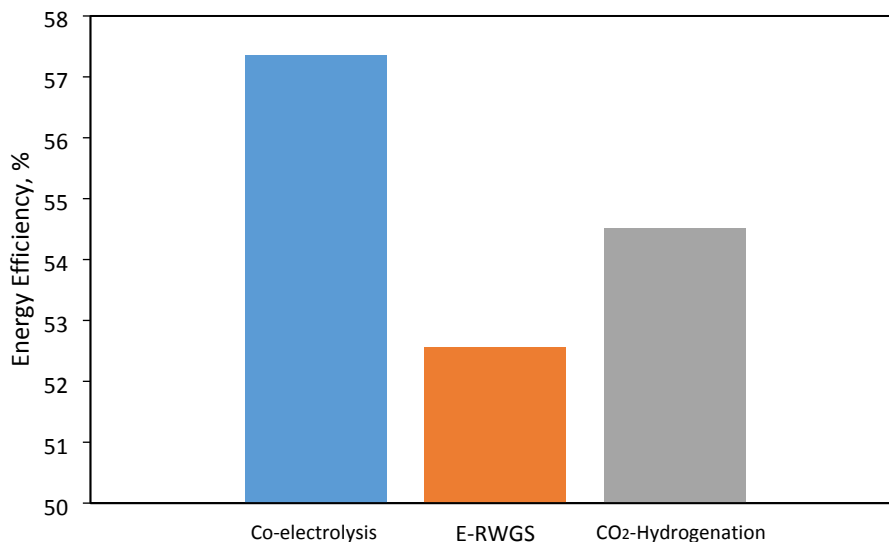

837 further rendering these reactors to operate at higher residence time than R3 and in contrast to R1, R2 and
838 R3 of both configuration 7B, 8 and syngas-based flowsheet. For CO₂ hydrogenation-based flowsheet 7B
839 and 8, conversion increases from first stage to last stage, with the last reactor stage having the highest single
840 pass conversion compared to other reactors. However, the trend is opposite for the syngas-based reactor
841 system. The second stage reactor has the highest conversion followed by the first stage and the last stage
842 reactor.

843 **3.4. Comparison of CO-rich route based on e-RWGS and Co-electrolysis-based process to** 844 **the optimal CO₂ rich PtMeOH route.**

845 Production of CO-rich syngas can be done by either using a RWGS reactor or SOEC via co-electrolysis.
846 Co-electrolysis offers a resource-saving and regenerative alternative to conventional syngas production.⁷⁴⁻
847 ⁷⁵ The syngas delivered by co-electrolysis can be easily varied by changing the ratio of CO₂/H₂O and it is
848 in the range (H₂: CO at 1:1 to 3:1) desired for methanol synthesis. For fair comparison, the syngas feed
849 coming from the electrolysis and e-RWGS was adjusted to 25.4/5.0/69.2% of CO/CO₂/H₂ with 0.4% H₂O
850 to ensure similar methanol production rate as the CO₂ based process while maintaining the syngas ratio of
851 2.1. Co-electrolysis is currently investigated in the current second phase of the Kopernikus project “P2X”
852 at the Energy Lab 2.0 at the Karlsruhe Institute of Technology (KIT).⁷⁴ Herein the energy efficiency of the
853 co-electrolysis is compared to the optimal direct PtMeOH process and the process with e-RWGS. Recently,
854 Haldor Topsoe has highlighted its interest in developing a renewable energy electrified reverse water gas
855 shift reactor (e-RWGS).⁷⁶⁻⁷⁷ The utilization of an e-RWGS reactor in methanol synthesis follows the
856 CAMERE process relying on fire heated RWGS reactors.⁷⁶ Basini et al. evaluated the potential of this step
857 but never compared it to other trending technologies such as co-electrolysis and CO₂-based PtMeOH overall
858 processes under similar basis.⁷⁶ This section will discuss this comparison as it was modelled in this work.
859 The SOEC-based co-electrolysis, steam electrolysis with and without e-RWGS are compared.

860
861 Figure 13: Energy efficiency comparison of co-electrolysis, e-RWGS, and CO₂ based power to methanol
862 process.

863 Following from Figure 13, the co-electrolysis-based process has the highest energy efficiency followed by
864 the SOEC steam electrolysis-based CO₂-hydrogenation and lastly the e-RWGS process. This is because
865 the syngas produced from co-electrolysis in the SOEC has the higher heating value and the SOEC uses less
866 heat under co-electrolysis compared to the steam electrolysis despite the co-electrolysis having higher
867 electricity consumption.⁵⁰

868 However, following from previous analysis, co-electrolysis may be flexible in terms of feed stock but for
869 regions with largely fluctuating electricity up to very low loads, steam electrolysis-based methanol is
870 recommended than the co-electrolysis-based process due to higher flexibility range of the CO₂
871 hydrogenation-based methanol process and the low power requirements for the SOEC steam electrolysis
872 compared to SOEC-based on co-electrolysis mode as discussed in section 3.1. However, other factors may
873 come into play such as the site-specific conditions, CO₂ emission reduction targets of the process and
874 desired production rates.⁷⁸⁻⁷⁹

875 4. CONCLUSIONS

876 This work has compared twelve different SOEC-based power-to-methanol process configurations. The
877 performance of the SOEC under steam- and co-electrolysis-based operation were first modelled and
878 compared. The results shows that steam electrolysis uses less power than the co-electrolysis. However, the
879 co-electrolysis based SOEC leads to the highest energy efficiency. Following from this, different adiabatic
880 reactor configurations based on CO₂ hydrogenation were compared. Among these configurations, parallel-

881 parallel, parallel-series and series-series based configurations were integrated with the SOEC unit operating
882 under steam electrolysis and compared considering the overall energy efficiency, conversion, production
883 rate, and single pass conversion profiles. Three candidate process flowsheet featuring parallel-series and
884 series-series based configuration were selected for further comparison. The selected parallel-series
885 configurations (flowsheet 7) feature three reactors in which the first two are in parallel and in series with
886 the third adiabatic reactor.

887 The selected promising series-series configuration (flowsheet 7B and 8) features three reactors in series
888 with intermediate cooling and separation. Thereafter the sensitivity-based analysis or optimisation and heat
889 integration are performed on the most promising flowsheets. The series-series configuration showed low
890 utility requirements upon optimisation of the heat exchanger network. To further assess the potential of
891 these configurations, dynamic simulation was performed using Aspen Dynamics to assess their flexibility
892 in terms of load change and considering parameters such as load change flexibility range, time to steady
893 state, composition changes, heat duty, power of the main units, load dependent energy efficiency, and single
894 pass reactor conversion profile. The dynamic simulation also featured the comparison of CO₂
895 hydrogenation-based, and syngas (derived from co-electrolysis) based flowsheets. Time to reach steady
896 state was shorter for parallel-series configuration compared to series-series configuration but the allowable
897 load flexibility range (40-105%) is similar for all the three CO₂-based configurations. This indicates the
898 potential to reduce the size of the intermediate product storage (e.g., H₂ storage) and allowing more flexible
899 direct coupling of the electrolysis and methanol synthesis sections. The syngas-based flowsheet, although
900 similar in architecture to the CO₂ hydrogenation-based flowsheet 8, cannot be ramped down to below 45%
901 of the nominal load. Flowsheet 8 had the highest load dependent energy efficiency and reduced instabilities
902 (undershoots and overshoots). Conversion increases with reduced load for all flowsheets. Overall,
903 considering all factors, the series-based configuration with three adiabatic reactors in series is the most
904 promising configuration. Multistage reactors offer the opportunity to promote flexibility by reducing the
905 reactor overdesign, and allow for operating one reactor per time based on the available power supply and
906 allowable idle period/downtime as may be set to prevent reactor damages and potential catalyst
907 deactivation.

908 5. FUTURE WORK

909 Future work must conduct techno-economics of the flowsheets to better discriminate among the three
910 candidate flowsheets for CO₂ hydrogenation. Furthermore, when the stoichiometric SOEC steam
911 electrolysis-based integrated methanol synthesis is compared to co-electrolysis-based and to the e-RWGS-
912 based configurations, the e-RWGS showed worse performance in terms of energy efficiency.

913 Although it has been demonstrated in this work that reactor configuration plays an important role in the
914 performance of the dynamic power-to-methanol process, especially when the high efficiency electrolyser
915 technology is used, more work is required to understand the dynamic operation strategies such as cold start-
916 up, warm-standby, hot-standby and shutdown, and their effect on degradation and profitability of the
917 process. For example, in the case of power-to-methanol operated with variable electricity, the reactor may
918 need to be kept at stand-by mode to avoid condensation for example by recirculating the feed by means of
919 bypassing the separator and shutting the purge thereby creating a batch system. Due to the enormous amount
920 of energy required by the power-to-methanol via CO₂ hydrogenation, opportunities exist to further optimise
921 the energy efficiency of the system with the intermediate product storage included. This must be assessed.

922 From the dynamic flexibility study conducted for the methanol synthesis section in this paper, it emanates
923 that power to methanol will offer both flexibility and long-term energy storage in future markets. More
924 data on hydrogen production are needed to further optimize the process. Future work should consider effects
925 of perturbation of the feed conditions on the dynamics of the hot-spot temperature and methanol production
926 from the low-cost adiabatic reactor as may be prevalent in the cases where variable power is used in power-
927 to-methanol process. This includes variation of H₂-to-CO₂ ratio. The H₂-to-CO₂ ratio may be a major
928 manipulable parameter in the case when renewable energy is used in power to methanol system. In this
929 study, the CO₂ is assumed continuous and thus dynamic effects as well as the associated CO₂ storage are
930 not considered. Future work should also consider the comparison of the heat integration potential when
931 using water-cooled reactor which generates medium pressure steam against the adiabatic reactor in the case
932 of power-to-methanol, in particular the steam utilization effect of coupling medium pressure steam to
933 SOEC. This should also consider the thermal inertia in the catalyst and its effect on the process performance.

934 In addition, because of different loads, the time co-ordination of heat recovery between various heat sources
935 and sinks must be assessed as well as its associated economics and energy efficiency. This study considered
936 constant pressure drop in the reactor. It would be necessary to consider variation in the pressure drop and
937 effect of modifying the reactor design, e.g., internals, on the optimization of the proposed load flexible
938 design. Future work should also consider integrating stochastic forecasting market model to the flexible
939 process for advantageous response to different electricity prices and methanol selling prices. This can also
940 be coupled with methanol fuel cells. In this work, simplified models were used to study the best
941 configuration with minimal complexity and thus future work must consider more detailed (e.g. 2D) models
942 including improved kinetic models (formulated with dynamic experimental conditions as well non-
943 negligible heat and mass transports) for better optimisation of the load flexible reactor configuration while
944 considering the sample electricity variation cycle and its corresponding H₂ and CO₂ production from the
945 coupled electrolysis and capture processes, respectively. Other intensification methods such as structured
946 reactors/catalysts must also be investigated and compared. It would also be interesting to understand the

947 significance of methanol reactor dynamics on the overall integrated efficiency of the PtMeOH process and
948 quantify the benefit in terms of the overall plant availability.

949 **DECLARATION OF COMPETING INTEREST**

950 The authors declare that they have no known competing financial interests or personal relationships that
951 could have appeared to influence the work reported on this paper.

952 **ACKNOWLEDGEMENTS**

953 This work was supported by the South African Department of Science and Innovation (DSI) for research
954 activities under the HySA Infrastructure Centre of Competence (KP5 program, Project No. CNMH17X)
955 and by the Council for Scientific and Industrial Research (CSIR) (Project Nos: C1GEN25, C8GOH26).

956 **SUPPLEMENTARY MATERIAL**

957 The Supporting Information is available free of charge on the attached supplementary material document.

Nomenclature

Symbol	Meaning (Unit)
AWE	Alkaline-water based electrolyser (–)
b_i	Logarithmic Arrhenius constants(–)
e-RWGS	Electrified Reverse Water Gas Shift Reactor
ΔG	Gibbs free energy (J mol^{-1})
ΔH_r	Heat of reaction (kJ mol^{-1})
COR	Carbon oxide ratio (–)
GHSV ₀	Gas hourly space velocity at nominal standard conditions (h^{-1})
GHSV	Gas hourly space velocity ($\text{NL.h}^{-1}.\text{gcat}^{-1}$)
HEN	Heat Exhnager Network
LCOM	Levelised cost of methanol ($\$/\text{tMEOH}$)
k_j	Reaction rate constant (–)
K_i	Adsorption constant (–)
M_{w_i}	Molecular weight (kg mol^{-1})
m_c	Mass of the catalyst (kg)
m_i	Mass of component (kg)
PteMeOH	Power to methanol
R	Ideal gas constant ($\text{J mol}^{-1}\text{K}^{-1}$)

RKSMHV2	Redlich-Kwong Soave with Modified Huron-Vidal mixing rules
SN	Stoichiometric number (–)
T	Temperature (K)
SOEC	Solid oxide electrolyser (–)
ε	Fixed bed porosity (–)
ρ_{cat}	Catalyst density (kg m^{-3})
