Recognition of trace organic pollutant and toxic metal ions *via* a tailored fluorescent metal–organic coordination polymer in water environment†

Danfeng He,^{ab} Shumei Liu,^a Fujiang Zhou,^c Xianjun Zhao,^c Yiwei Liu,^a Fang Luo^a and Shuxia Liu^{id}*^a

A novel fluorescence material $\text{H}_2\text{Sr}_2(\text{bqdc})_3(\text{phen})_2$ (**1**) for trace recognition of organic pollutant and toxic metal ions is designed and prepared by two weak fluorescent ligands and Sr^{2+} . The latter was selected although it played no role in the modulation process of luminescence and despite low-cost, alkaline earth, metal–organic coordination polymers lacking competitive functionality. The strong fluorescence of the fluorescence material was based on the propeller configuration of the metal–organic coordination polymer, which was characterized by X-ray single crystal diffraction showing that the N active sites inside the crystal channels can interact with external guests. Convenient fluorescence detection of 3-AT can be realized using an ultraviolet lamp and test strip and the determination of Cd^{2+} showed good reusability with a detection limit of $1 \times 10^{-9} \text{ mol L}^{-1}$, which is lower than the standard stipulated by the Environmental Protection Agency. Detailed experiments results revealed that the material was a promising candidate for specifically recognizing amitrole and Cd^{2+} because of its selective fluorescence quenching and sensitive detection in water.

Introduction

As a result of global development of industrial and agricultural production, the intensity of environment pollution is becoming increasingly serious.¹ Toxic organic and inorganic contaminations in water environment are one of the most problematic issues because of their negative effect on the human body. An example of such an organic pollutant is amitrole (3-AT), a widely used herbicide that has strong biological toxicity and carcinogenicity, and can enter the human body when dissolved in water.² A well-known example of heavy-metal poisoning is the itai-itai disease (itai = pain in Japanese), which was originally caused by cadmium pollution in the Jinzhu River Basin in Japan, and is chronic cadmium poisoning caused by long-term consumption of polluted water.³

The water quality of samples needs to be determined using an appropriate standard.⁴ Therefore, it is important to develop effective and efficient detection methods to measure pollution

levels. To date, various techniques have been used for this purpose, including electrochemistry,⁵ mass spectroscopy,⁶ gas chromatography,⁷ ion mobility spectrometry,⁸ biological detection⁹ and other techniques.¹⁰ Because of its high sensitivity, low cost and simple pretreatment, fluorescence sensing technology has attracted considerable attention in water-quality detection.¹¹

Fluorescent metal–organic coordination polymers (MOCPs) have shown huge potential in chemical sensing because their hybrid structures can offer tunable fluorescence, and have been extensively studied for sensing molecules,¹² metal ions,¹³ gases,¹⁴ vapors¹⁵ and explosives,¹⁶ *etc.* With well-defined constructions, dense packed pore structures, excellent stability and potential optical properties, luminescence MOCPs have attracted increasing attention due to the promise they show in sensing. Very recently, MOCPs-based sensing materials have showed very promising results in detection of organic molecules or metal ions in water.¹⁷ Well-defined MOCPs possess unique, tunable optical properties, and their strong fluorescence intensity and internal active sites are advantageous for fluorescence sensing.¹⁸

Researchers are eager to obtain fluorescence MOCPs with the configuration of a propeller.¹⁹ Non-planar fluorescent molecules are often characterized by an aggregation-induced emission (AIE) effect; in particular, a propeller configuration can largely prevent close $\pi \cdots \pi$ interactions, thereby inhibiting nonradiative deactivation, leading to fluorescence

enhancement.²⁰ However, it is difficult to synthesize molecules with a propeller configuration.

In this work, we select a rigid bqdc (2,2-biquinoline-4,4-dicarboxylic acid) with the active site N and fan-shaped phen (1,10-phenanthroline) to construct a MOCP, along with alkaline earth metal ion Sr²⁺. Single crystal X-ray diffraction analysis reveals that the asymmetric unit of title complex **1** was a propeller configuration with fan-shaped construction, including two crystallographically independent Sr²⁺ ions, three bqdc²⁻ ions and two phen molecules, and there are many N active sites in the channels of **1**.

The desired target molecule with a propeller configuration is obtained, and determined by X-ray single crystal diffraction measurement. The N active sites are observed in the channels of the crystal, which can play an important role in interacting with external guests. Such fluorescent MOCPs with active sites are attractive for use in sensing.

For ligand-based fluorescent MOCPs, most research was in the view of single ligand with strong fluorescence.²¹ Few researchers have used two or more ligands with weak fluorescence in fluorescence detection. Herein, two ligands with weak fluorescence and non-luminous Sr²⁺ were employed to prepare fluorescence MOCP, which showed good fluorescence properties and sensing responses to specific organic pollutant 3-AT and toxic cadmium(II) metal ion.

Experimental

Materials and methods

The ligands 2,2-biquinoline-4,4-dicarboxylic acid, 1,10-phenanthroline and Sr(NO₃)₂ were purchased from Sinopharm (Shanghai) Chemical Reagent Ltd., China. All other chemicals were of analytical grade quality, and were obtained from commercial sources and used without further purification. Deionized water was used in all experiments. All other chemicals were obtained from commercial suppliers without further purification unless otherwise noted.

The infrared spectra in KBr pellets were recorded in the range of 400–4000 cm⁻¹ with an Alpha Centauri FT/IR spectrophotometer. Elemental analysis (C, N and H) was performed on a Perkin-Elmer 2400 CHN elemental analyser. Powder X-ray diffraction measurements are performed on a Rigaku D/MAX-3 instrument with Cu-K α radiation in the angular range $2\theta = 3\text{--}60^\circ$ at 293 K. Thermogravimetric analysis were carried out by using a Perkin-Elmer TGA instrument with a heating rate of 10 °C min⁻¹ under nitrogen atmosphere. Photoluminescence spectra were measured using a FLSP 920 Edinburgh instrument (Eng) with a 450 W xenon lamp monochromatized by double grating. All the excitation and emission slits of the experiments were set to 5.0 nm. In fact, just recording some emission spectra and comparing the intensities is not very reliable when it does not ensure that the experimental settings of the spectrometer are exactly identical and the number of photons absorbed by each sample are the same. This is particularly challenging for solid powdered samples.

Synthesis of H₂Sr₂(bqdc)₃(phen)₂

A mixture of Sr(NO₃)₂ (0.021 g, 0.10 mmol), bqdc (0.15 mmol), phen (0.10 mmol), HNO₃ (0.10 mL) and water (15 mL) was stirred for 1 h in air, then sealed in a 25 mL Teflon-lined stainless steel container, which was heated to 155 °C for 72 h. After cooling to room temperature at a rate of 5 °C h⁻¹, colourless rhombus crystals **1** were obtained with ca. 68% yield (based on bqdc). Anal. calc. for C₈₄N₁₀O₁₂H₄₈Sr₂: C, 64.48; H, 3.09; N, 8.95%. Found: C, 64.52; H, 3.11; N, 9.01%. IR (KBr disks): 3363s, 2895s, 1504s, 1046s, 861s, 772s.

Fluorescence detection of organic contaminants

Different organic contaminants including 3-AT, 1,4-dinitrobenzene (1,4-NB), 2,4,6-trinitrotoluene (TNT), triethylamine (Et₃N), hexane (Hex), toluene (PhMe) and ethyl acetate (EtOAc) were respectively added to water to form 0.001 mol L⁻¹ solutions. Complex **1** was added to each solution to give a concentration of 0.001 mol L⁻¹. Each solution was stirred for 30 s and then an aliquot (3.50 mL) was taken out and put in a cuvette for fluorescence spectroscopy measurements. All fluorescence measurements was performed under the same conditions.

Fluorescence detection of inorganic contaminants

Samples of **1** (0.0005 mmol) were soaked in solutions (10 mL) containing 0.001 mol L⁻¹ MCl_x (M = Cd²⁺, Cu²⁺, Fe³⁺, Mn²⁺, Ni²⁺, Pb²⁺, Sb²⁺, Ba²⁺ or Zn²⁺) with stirring for 30 min. The microcrystalline solids were collected by centrifugation, and dried at 100 °C for 1 h. The fluorescence of each treated sample was measured under the same conditions.

Single-crystal X-ray crystallography

Single-crystal diffractometry was conducted on a Bruker Smart Apex CCD diffractometer with Mo K α monochromated radiation ($\lambda = 0.71073 \text{ \AA}$) at room temperature. The linear absorption coefficients, scattering factors for the atoms, and anomalous dispersion corrections were taken from the International Tables for X-ray Crystallography.²² Empirical absorption corrections were applied. The structures were solved by using the direct method and refined through the full matrix least-squares method on F² using SHELXS-97.²³ The detailed crystal information and structure refinement results of H₂Sr₂(bqdc)₃(phen)₂ (**1**) are presented in Table 1. Further details of the structural analyses can be obtained from the depository numbers: CCDC 1059044.

Results and discussion

Characteristics of H₂Sr₂(bqdc)₃(phen)₂

Single crystal X-ray diffraction analysis reveals that the title complex, **1**, crystallizes in the triclinic space group *P* $\bar{1}$. The asymmetric unit of its construction contains two crystallographically independent Sr²⁺ ions, three bqdc²⁻ ions and two phen molecules. It is worth reminding that there are many N active sites in the channels of **1** (Fig. 1), and the solvent accessible volume is about 22.7% as determined by PLATON.²⁴

Fig. 1 Illustration of the MOCPh₂Sr₂(bqdc)₃(phen)₂. All of the H atoms are omitted for clarity.

Obviously, this complex possessed a porous structure with suitable dimensions to improve accessibility of the external metal ions to the active sites and increase the response rate to specific recognition.

With rigid fan-shaped structure, six bqdc and two phen coordinated with a Sr²⁺ cluster centre to form a segment of H₂Sr₂(bqdc)₃(phen)₂, which shows a very interesting configuration similar to a propeller as shown in Fig. 2a. Complex 1 does not dissolve in water, and the thermogravimetric analysis (TGA) revealed that 1 is a good heat-resistant material until 200 °C, which is stable enough to allow external ions or

Fig. 2 (a) The crystal structure of the title complex. (b) The emission intensities of phen, bqdc and H₂Sr₂(bqdc)₃(phen)₂.

molecules to enter inside its channels (Fig. S1†). The powder X-ray diffraction (XRD) pattern of as-synthesized 1 was identical to the simulated data, indicating that the structural integrity of 1 is maintained (Fig. S2†).

Fluorescence properties

The emission spectra of ligands bqdc and phen showed weak fluorescence peaks with a maxima at 403 nm ($E_x = 266$ nm) and 363 nm ($E_x = 297$ nm), respectively (Fig. S3 and 4†). Both of these broad peaks were ascribed to $\pi \cdots \pi^*$ electronic transitions inside the ligands. The emission spectrum of complex 1 contained peaks at 426 and 492 nm ($E_x = 365$ nm) (Fig. S5†). The red shift and enhanced intensity of emission observed for 1 are attributed to the increased rigidity of the ligands upon coordination with the alkaline earth metal ion Sr²⁺, which suppresses intramolecular proton transfer.²⁵ Surprisingly, compared with the emission intensities of bqdc and phen, the emission intensity of 1 greatly increased by around 21 or 101 times, respectively (Fig. 2b). It is believed that the propeller configuration of 1 limited the close $\pi \cdots \pi$ interactions at the most extent, which extremely decreases the amount of energy lost through nonradiative decay and thus enhances the intensity of fluorescence emission from 1 compared with that from the ligands.

Fluorescence responses to organic molecules

Considering the strong emission and good stability of 1, we examined its fluorescence responses to organic molecules, which can potentially affect human health and environmental quality. A series of fluorescence spectroscopy measurements were performed in aqueous solution using different organic molecules including amitrole (3-AT), 1,4-dinitro-benzene (1,4-NB), 2,4,6-trinitrotoluene (TNT), triethylamine (Et₃N), hexane (Hex), toluene (PhMe) and ethyl acetate (EtOAc). The experimental process has been described in Section 2.3. The experimental results showed that indistinct emission decrease occurred for all of the organic molecules except 3-AT. Indistinctive emission decrease (40.57% for 1,4-NB, 31.64% for TNT, 12.81% for EtOAc, 12.01% for Hex, 6.78% for PhMe and 9.10% for Et₃N) was observed for other organic molecules. Remarkably, a distinct emission change was observed for 3-AT, with 98.58% quenching of emission intensity (Fig. 3, S6 and Table S1†). According to a large number of repeated experiments with

Fig. 3 Fluorescence responses of the complex with different organic molecules. ($1 \times 10^{-3} \text{ mol L}^{-1}$, excited at 365 nm).

similar results, the fluorescent quenching of **1** by 3-AT clearly reveals that **1** can recognize 3-AT in water.

The fluorescence of complex **1** in mixtures of tetrahydrofuran and hexane with different proportions was also investigated. The luminescence of the solutions became weaker as the proportion of tetrahydrofuran increased, and strengthened as the content of hexane rose (Fig. S7[†]). This indicates that complex **1** follows the AIE effect, so it is logical that quenching is observed in the sensing process using **1**. When organic molecules interact with the coordination polymer, they further dilute the samples to some extent, and hinder the AIE effect in **1**, leading to the reduced fluorescence intensity. In the case of 3-AT, its three N active sites can coordinate with Sr^{2+} of the host framework and displace the original ligands through competitive coordination substitution.²⁶ The ligand is released from the metal ion, causing the collapse of the framework and the quenched fluorescence, which is consistent with the XRD results for **1** (Fig. S8[†]).

The fluorescence response of **1** to organic molecules *in situ* testing was studied. To simplify the detection procedure, a small amount of **1** was paved on a paper strip to form a spot, then a solution containing contaminant was added drop wise into the spot containing **1**. The quenching of fluorescence from **1** upon addition of 3-AT was observed clearly in a short time under an ultraviolet lamp (Fig. S9[†]). Conversely, test strips exposed to 1,4-NB, TNT, Et_3N , Hex, PhMe and EtOAc did not show any obvious fluorescence change of **1**. These experiment results reveal the potential of **1** for real-time monitoring of 3-AT with easy steps.

Fluorescence responses to toxic metal ions

Considering that **1** contains N active sites, its utility for detection of toxic metal ions was evaluated. The experiment process has been described above in Section 2.4. The fluorescence intensity of **1** did not decrease noticeably when it was exposed to M^{n+} except in the case of Cd^{2+} . The interaction with Cu^{2+} , Fe^{3+} , Mn^{2+} , Ni^{2+} , Pb^{2+} , Sb^{2+} , Ba^{2+} or Zn^{2+} showed quenching efficiency of 17.12%, 22.03%, 12.20%, 9.29%, 6.37%, 11.29%, 3.46% and 10.29%, respectively. For Cd^{2+} , the fluorescence intensity of **1** was almost completely quenched, with a quenching efficiency of 99.02% (Fig. 4).

Fig. 4 Fluorescence responses of the complex with different toxic metal ions ($1 \times 10^{-3} \text{ mol L}^{-1}$, excited at 365 nm).

For further comparison, the quenching effect of **1** by various metal ions with concentrations ranging from 1.0×10^{-9} to $1.0 \times 10^{-2} \text{ mol L}^{-1}$ was investigated (Fig. S10[†]). As the concentrations of metal ions increased, the fluorescent intensity of **1** decreased gradually; that is, quenching efficiency slowly increased. (Fig. S11, Table S2[†]). For Cd^{2+} , the fluorescence intensity of **1** decreased a little at a Cd^{2+} concentration of $1.0 \times 10^{-9} \text{ mol L}^{-1}$, indicating the highly sensitive detection ability of **1** for Cd^{2+} . When the molar ratio of Cd^{2+} to complex **1** reached the equivalence point of 2 : 1, the fluorescence of **1** was almost completely quenched, and further increasing the Cd^{2+} concentration did not lead to any change of fluorescence (Fig. 5).

The results of repeated experiments were the same, confirming that **1** has the potential to detect Cd^{2+} in the presence of other metal ions in aqueous solution. The detection limit of **1** for Cd^{2+} is $1 \times 10^{-9} \text{ mol L}^{-1}$ (0.0002 mg L^{-1}), which is below the drinking water standard stipulated by the EPA (Environmental Protection Agency) (0.0050 mg L^{-1}).²⁷

An important structural feature of **1** is the active sites within the pores that allow recognition of metal ions to achieve sensing, and the fluorescence measurements revealed that selective quenching of the fluorescence of **1** by Cd^{2+} is traceable.

Fig. 5 Fluorescence responses of complex with Cd^{2+} metal ion with different concentrations (excited at 365 nm).

Scheme 1 The fluorescence quenching mechanism simulation of the complex with Cd^{2+} metal ion.

As previously mentioned, the N active sites of ligand bqdc are dispersed in the channels of **1**. To explore the mechanism of luminescence quenching, we evaluated the interaction between active sites and guest ions. Regarding the quenching mechanism of **1**, it can be deduced that the active sites of bqdc interacted with external metal ions to achieve a sensing effect, which was also predicted in a simulation (Scheme 1). The strong interaction between the N active sites and Cd^{2+} can perturb the electronic structure of the ligand considerably, and then enhance the efficiency of energy transfer from the ligand to Cd^{2+} . This promoted intramolecular energy transfer in **1**, leading to the fluorescence quenching. These findings are similar to those mentioned in previous work reported including that by our group.²⁸

The reusability of a sensing material is of great importance to commercial feasibility.²⁹ Complex **1** showed excellent reversibility upon simply washing with ethanol or deionized water several times. It was observed that **1** was still stable after being reactivated four times, as confirmed by infrared spectroscopy and XRD patterns (Fig. S12 and S13[†]).

Conclusions

Fluorescent material **1** was synthesized from a non-luminous alkaline earth metal ion, Sr^{2+} , and two weak fluorescence ligands bqdc and phen. Its propeller structure can help to limit the close $\pi \cdots \pi$ interactions that decreased nonradiative decay, greatly enhancing the emission intensity of **1** compared with that of the uncoordinated ligands. Experiments illustrated that **1** can specifically recognize 3-AT and Cd^{2+} through fluorescence quenching. The quenching mechanism involved competitive coordination substitution and intramolecular energy transfer. The strong fluorescence intensity, selective fluorescence alteration, appropriate stability and sensitive detection of **1** make it a promising candidate as sensors for specifically recognizing organic pollutant 3-AT and quantitative detection of toxic Cd^{2+} in water. Moreover, 3-AT can be conveniently detected by an ultraviolet lamp and test strip, and Cd^{2+} can be sensed with good reversibility and reproducibility with a detection limit of $1 \times 10^{-9} \text{ mol L}^{-1}$. The present study represents a large step forward in the effort to develop novel MOCPs for use as fluorescence sensors. Further investigations on modulating the optical properties of MOCPs, especial ligand-based ones, are underway.
