# Mn<sub>3</sub>O<sub>4</sub>/graphene nanocomposites: outstanding performances as highly efficient photocatalysts and microwave absorbers†

Ahmed A. Amer, S. M. Reda, M. A. Mousa and Mohamed Mokhtar Mohamed\*

Mn<sub>3</sub>O<sub>4</sub> (M) incorporated graphenes (G) synthesized by a deposition–solvothermal process, formed at various nominal weight percentages (G1M1, G3M1 and G1M3), were efficiently used for the photodegradation of methylene blue dye (MB) under visible light illumination ( $\lambda > 420$  nm, 88 W, 20 ppm, 298 K) and under microwave irradiation (800 W, 2.45 GHz, 373 K). These materials were characterized using XRD, TEM-SAED, UV-Vis diffuse reflectance, N<sub>2</sub> sorptiometry, FTIR and Raman techniques. Amongst the nanocomposites, G3M1 of polyhedral structure and an average domain equal to 10–12 nm has presented unique photo-degradation performance (100% degradation, 60 min, 0.0791 min<sup>−1</sup> and TOC of 60%) exceeding the rest of the materials. This was mainly due to the extraordinary optical properties and to the strong interaction between Mn<sub>3</sub>O<sub>4</sub> and graphene through which charge recombination is hampered. Based on the conduction and valence band edges together with the studied reactive species, it has been shown that  $\cdot\text{OH}$  was the dominant species responsible for the MB degradation. Interestingly, the G3M1 nanocomposite has shown fascinating microwave absorption properties and is capable of degrading MB at a faster rate (0.287 min<sup>−1</sup>) than the one conducted via photocatalysis. Scavenger studies have shown that  $\cdot\text{OH}$  and electrons were responsible for the excellent performance of the MB microwave degradation. The microwave results were discussed in view of the marked increase in dielectric constant ( $\epsilon'$ ) and dielectric loss ( $\epsilon''$ ) in the studied frequency range of 1.0 Hz to 100 kHz, in addition to the electronic conductivity measurements. This work offers an exceptional approach for exploring high-performance microwave absorption as well as distinctive visible light photocatalytic reaction for organics degradation.

## 1. Introduction

The advances in industrial processes generate enormous amounts of highly toxic organics that pollute the aquatic environment. Photocatalysis as one of the promising green technologies,<sup>1,2</sup> has attracted the attention of many researchers due to its ability to decompose organic pollutants into CO<sub>2</sub> and water. So far, TiO<sub>2</sub> is a widely employed photocatalyst due to its superiority in oxidation power, nontoxicity, durability and stability.<sup>3</sup> However, TiO<sub>2</sub> limitation due to its restricted activation in near UV region as well as the high recombination of its electron–hole pair hinders its photocatalytic applications under visible irradiation.<sup>4</sup> Thus, great effort has been dedicated to develop unique photocatalysts, which could exhibit higher activity under visible light illumination.<sup>5</sup> Among them, Mn-based catalysts especially Mn<sub>3</sub>O<sub>4</sub> is known to be an effective catalyst for de-NO<sub>x</sub> reactions, raw materials for electronics and

information devices.<sup>6</sup> Nanosized Mn<sub>3</sub>O<sub>4</sub> was also reported as a high-capacity anode material for rechargeable lithium batteries.<sup>7</sup> In spite of the high catalytic performance of Mn<sub>3</sub>O<sub>4</sub> nanoparticles (NPs), poor chemical and thermal stabilities of the material have stimulated the aggregation of NPs and thus, lessening their catalytic efficiencies.<sup>8</sup> In addition, increasing the band-gap energy of Mn<sub>3</sub>O<sub>4</sub> was generally uncontrollable and used to change as a function of the structure and/or the support. To get over these obstacles, carbonaceous materials especially graphene was exploited to support Mn<sub>3</sub>O<sub>4</sub> due to its high surface area and high electrical conductivity value.<sup>9–11</sup> This hybrid between graphene and Mn<sub>3</sub>O<sub>4</sub> has generated remarkable interest because of their synergistic effects in activating the electrocatalytic reduction of oxygen,<sup>12</sup> catalytic decomposition of organics, and as storage of charges in supercapacitors.<sup>13,14</sup> However, some limitations affected the performances of this hybrid most importantly, rapid and reversible transformation of the reduced phase (Mn<sub>3</sub>O<sub>4</sub>) with the other oxidized forms (Mn<sub>2</sub>O<sub>3</sub>, MnO<sub>2</sub>)<sup>15</sup> and the morphological deficiencies based on preparing various structures of Mn<sub>3</sub>O<sub>4</sub> with high particles domain.<sup>16</sup> As a consequence, the hybrid Mn<sub>3</sub>O<sub>4</sub>/graphene never shows a photocatalytic oxidation to a dye under visible light

irradiation as well as without oxidants such as  $\text{H}_2\text{O}_2$  and peroxymonosulfate (PMS).<sup>9,14</sup> Although these oxidants are environmentally friendly, they have some drawbacks such as cost-effective, transport, storage, and pH adjusting requirements.<sup>17</sup> In view of the mentioned deficiencies, we synthesized magnificent photocatalysts composed of  $\text{Mn}_3\text{O}_4$ /graphene nanocomposites *via* a facile non-template deposition-solvothermal route for the purpose of increasing the contacts between the 2D graphene nano-sheets and  $\text{Mn}_3\text{O}_4$  moieties. This indeed is expected to facilitate the electron transfer from the latter to that of the former; hindering  $\text{e}^-$ - $\text{h}^+$  recombination, and thus can be employed in methylene blue oxidation in the absence of any oxidants under visible light illumination.

It has been shown that microwave (MW) absorption for some materials can play significant role in wastewater treatment and thus can save time and energy. During the previous decade, MW absorbing materials known as dielectrics have been the subject of great interest particularly for their marked roles in wastewater treatment. Materials, such as activated carbon,<sup>18,19</sup> CNTs<sup>20,21</sup> and polymers<sup>22</sup> are frequently employed in microwave-assisted degradation of organic pollutants. Among MW absorbers,  $\text{MFe}_2\text{O}_4$  are the most capable<sup>23</sup> because of the chemical properties of  $\text{M}^{2+}$  and  $\text{Fe}^{3+}$  and to the high magnetic permeability or electrical resistivity.<sup>24</sup> Accordingly,  $\text{MnFe}_2\text{O}_4$ -SiC has shown high MW absorption that assisted the degradation of RBR X-3B with an efficiency equal 92%. However, this catalyst suffers low stability.<sup>25</sup> Therefore, looking for other materials of higher MW absorbers and higher degradation performances is an essential task. Manganese oxides [ $\text{MnO}_6$ ] have shown good degradation performances for methylene blue under microwave irradiation based on the significant difference in the oxidative removal ability between akhtenskite and birnessite phases.<sup>26</sup> However, the hybrid between graphene and  $\text{Mn}_3\text{O}_4$ ; the most common dielectric and microwave attenuation material, has rarely been reported. Herein, we demonstrate the interfacial coupling between  $\text{Mn}_3\text{O}_4$  and graphene for the purpose of improving the dielectric properties of the nanocomposites and for microwave-enhanced oxidation of the MB dye with high reaction rates, short reaction times and great energy efficiency. These findings may open up an efficient improvement in the MW absorbers for rapid degradation of organic pollutants.

## 2. Catalyst preparation

### 2.1. Reduction of GO

Graphene oxide that was synthesized based on the modified Hummer's method was first dispersed in 30 mL distilled water and sonicated for 30 min.<sup>27</sup> This suspension was then heated to 100 °C followed by the addition of 3 mL hydrazine hydrate. The suspension was then kept at the latter temperature for 24 h. Consequently, the reduced graphene was collected by filtration in the form of black powders. The obtained material was thoroughly washed using distilled water for several times followed by sonication to remove the excessive hydrazine amounts. The final product was collected by vacuum filtration and dried at 80 °C.

### 2.2. Preparation of $\text{Mn}_3\text{O}_4$

4.9018 g (20 mmol) of  $\text{Mn}(\text{CH}_3\text{COO})_2 \cdot 4\text{H}_2\text{O}$  was dissolved in 100 mL ethanol. Then, 40 mL of  $\text{NH}_3 \cdot \text{H}_2\text{O}$  (25–28 wt%) was added into the previous solution to indicate changing of the colourless solution into to a light red without precipitation. An air purge at a rate equal 1.5 L  $\text{min}^{-1}$  was blown into the solution that heated up into 50 °C for 5 min. During this process, the solution colour changes gradually into a deep black with a consequent decomposition to form a colloidal solution of high dispersion and stability. Centrifugation and drying at 50 °C was then performed to produce the nano-sized  $\text{Mn}_3\text{O}_4$  crystals.

### 2.3. Synthesis of RGO/ $\text{Mn}_3\text{O}_4$

The RGO/ $\text{Mn}_3\text{O}_4$  composites were synthesized by solvothermal method *via* dispersing 20 mg RGO in 200 mL DMF followed by sonication for 30 min and heating to 80 °C. Addition of 20 mL of 0.2 M  $\text{Mn}(\text{Ac})_2 \cdot 4\text{H}_2\text{O}$  was attained while stirring that extends about 1 h to prepare different composite loadings. The as-made composites were treated as above *via* using both the ammonia solution and purging air followed by the heating step carried out at 50 °C for 5 min. These nanocomposites contained in 200 mL solution were autoclaved at 180 °C for 10 h. Then, the products were collected by centrifugation using ethanol, followed by drying at 60 °C for 48 h. The as-synthesized catalysts were denoted as G1M1, G3M1 and G1M3 where the numbers are denoted to the weight ratios.

### 2.4. Materials characterization

The X-ray powder diffraction patterns of various nanocomposites were carried out using a Philips 321/00 instrument and were run with Ni-filtered Cu K $\alpha$  radiation ( $\lambda = 1.541 \text{ \AA}$ ) at 36 kV. The surface properties specifically BET surface area, total pore volume ( $V_p$ ) and mean pore radius ( $r$ ) were determined from  $\text{N}_2$  adsorption isotherms measured at  $-196 \text{ }^\circ\text{C}$  using conventional volumetric apparatus. The pore size distribution was determined from desorption branch of the isotherm using the BJH analysis. Diffuse Reflectance Ultraviolet-Visible Spectroscopy (UV-Vis DRS) of nanocomposites together with the edge energy ( $E_g$ ) for allowed transitions were carried out at room temperature using a Perkin Elmer Lambda-900 spectrophotometer in the range of 200–800 nm. The Fourier transform infrared (FT-IR) spectra were recorded *via* a double beam Perkin Elmer Spectrometer with a resolution of 2  $\text{cm}^{-1}$  using the KBr method. Raman spectra were measured with a U-1000 laser Raman spectrometer using the 514.5 nm line of an ArC laser as the excitation beam. Selected area electron diffraction (SAED) images and TEM micrographs were measured using a FEI; model Tecnai G20, super twin at an accelerating voltage of 200 kV.

### 2.5. Photocatalytic degradation experiments

A high pressure Hg lamp of 88 W with a special UV cut off filter ( $\lambda > 420 \text{ nm}$ ) offering visible light source; with an average light intensity equal 40  $\text{mW cm}^{-2}$ , was placed at a specified position

using a special rod in the reactor. The photocatalyst (100 mg) was suspended in 100 mL aqueous solution of 20 mg L<sup>-1</sup> methylene blue (MB). The solution was stirred in the dark for 60 min to ensure the establishment of an adsorption-desorption equilibrium. During irradiations, 2 mL aliquots were removed at definite time intervals and analyzed with a Shimadzu UV-2350 spectrophotometer to measure MB concentrations. The degradation percentages were calculated based on the following equation: removal (%) =  $C_0 - C_t / C_0 \times 100$ ; where  $C_0$  and  $C_t$  correspond to the initial concentration and that at time  $t$ , respectively.

For exploring the reactive species might produced in the photocatalytic reaction,<sup>28</sup> we used different scavengers including isopropanol (a quencher of  $\cdot\text{OH}$ ), *p*-benzoquinone (a quencher of  $\cdot\text{O}_2^-$ ), triethanol-amine TEOA (a quencher of  $\text{h}^+$ ), and carbon tetrachloride (a quencher of  $\text{e}^-$ ) at a concentration of 1.0 mM.

## 2.6. Microwave degradation of MB

A quartz vessel containing 100 mL of MB solution (20 ppm) and 0.1 g catalysts was inserted into a Milestone Start D Microwave Digestion System operating at 800 W and 2.45 GHz. The samples are heated from room temperature to 100 °C in 5 min. This temperature was maintained while performing the reaction and then the samples were left to cool down to room temperature. The samples were then forwarded to the UV/Vis Spectrophotometer to analyze the residual MB in the wavelength region of 200–700 nm. The degradation percentages were calculated as above.

## 2.7. Electrical properties

The electrical properties of the prepared composites were demonstrated *via* compressing the powder of the sample under a pressure of 5 tons cm<sup>-2</sup> to build up pellets. The two equivalent surfaces of the pellets (7 mm diameter and 1 mm thickness) were coated with silver paste to ensure good electrical contact. The electrical measurements were carried out at a constant voltage (1 volt) in a frequency range from 1.0 kHz to 300 kHz and at the temperature of 25 °C; and if necessary raised to 100 °C, using a programmable automatic LCR bridge (HIOKI: 3532-50). The dc electrical resistivity was measured with an electrical circuit consists of an electrometer (model 6517, Keithley), voltmeter (Keithley, 2182) and 5 kV dc power supply. The dc-conductivity  $\sigma_{dc}$  of the material was calculated by the following equation  $\sigma_{dc} = (l/A_s)(1/R_{dc})$  where  $R_{dc}$  is the sample resistance,  $l$  is the length of the sample and  $A_s$  is the cross-sectional area. The complex dielectric permittivity was investigated through LCR meter (HIOKI: 3532-50) using the relation  $\epsilon^*(\omega) = \epsilon'(\omega) - j\epsilon''(\omega)$ ; where  $\epsilon'$  is the real part of the permittivity and  $\epsilon''$  is the imaginary part of the permittivity with  $j = \sqrt{-1}$ . The dielectric constant of samples was measured using the equivalent capacitance ( $C$ ). The values for  $\epsilon'$  and  $\epsilon''$  were estimated using the relations  $\epsilon' = (C/\epsilon^0)(d/A_s)$  and  $\epsilon''(\omega) = \epsilon'(\omega) \tan \delta$ ; where  $C$  is the capacitance of the sample,  $\epsilon^0$  is the permittivity of the vacuum,  $d$  is the thickness,  $A_s$  is the cross-sectional area of the specimen,  $\tan \delta$  is the dissipative factor where  $\delta$ -phase angle is

determined *via*  $\omega = 2\pi f$ , where  $f$  is the frequency of the applied electric field.

### 3. Results and discussion

### 3.1. Bulk and morphology study

Fig. 1 presents the X-ray diffraction (XRD) patterns of reduced graphene (RG), bare  $\text{Mn}_3\text{O}_4$  nanoparticles as well as the as-prepared RG- $\text{Mn}_3\text{O}_4$  nanocomposites. The diffraction peaks of RG seen at  $2\theta = 24.5^\circ$  and  $43.8^\circ$  due to 002 and 100 reflections of graphitic carbon were depicted evidencing the reduction of graphene oxide to graphene during the hydrazine-thermal process. The calculated average interlayer distance was found to be 3.63 Å. Broadening of graphene peaks after reduction is diagnostic for lowering RG stacking defaults. On the other hand, the XRD pattern of  $\text{Mn}_3\text{O}_4$  shows plenty of sharp peaks matched well with JCPDS no. 24-0734, indicating the formation of tetragonal Hausmannite-type  $\text{Mn}_3\text{O}_4$  with space group  $I4_1/amd$ . No peaks of any other phases or impurities are observed demonstrating that the adopted method is suitable for the preparation of pure  $\text{Mn}_3\text{O}_4$  phase. The latter phase elaborates diffraction peaks correspond to 101, 112, 200, 103, 211, 004, 220, 204, 105, 312, 303, 321, 224 and 400 planes. According to Scherrer analysis, the size of  $\text{Mn}_3\text{O}_4$  is estimated to be  $\sim 15$  nm. The nanocomposites RG- $\text{Mn}_3\text{O}_4$  patterns indicate the coexistence of both RG diffraction lines; especially the 002 line, as well as those of the  $\text{Mn}_3\text{O}_4$  phase. Vanishing of the 100 peak related to RG in all nanocomposites is indicative to the activity of the in-plane crystallite site. Increasing the  $\text{Mn}_3\text{O}_4$  ratio relative to RG indicated more disordered graphene sheets as noticed *via* deterioration and splitting of the 002 peak, evidenced in G1M1 and G1M3 samples. The XRD patterns of G3M1 and G1M1

**Fig. 1** XRD patterns of RGO,  $\text{Mn}_3\text{O}_4$ , G3M1, G1M1 and G1M3.

exhibited an increase in the Hausmannite  $\text{Mn}_3\text{O}_4$  crystallinity. Where in G1M3, a significant decrease rather than increase in the phase forming  $\text{Mn}_3\text{O}_4$  was depicted. A new peak at  $2\theta = 28.7^\circ$  corresponding to the 110 plane is appeared in G1M1 and indexed to the  $\alpha\text{-MnO}_2$  phase.<sup>29</sup> Another peak at  $2\theta = 75^\circ$  is seen in G1M1 and G1M3 samples ascribed to the 413 plane of  $\text{Mn}_3\text{O}_4$ ; never depicted in their bare forms. Accordingly, the lines intensification observed in G1M1 and G3M1 compared to the bare  $\text{Mn}_3\text{O}_4$  might give a hint about presence of other Mn species at similar positions of  $\text{Mn}_3\text{O}_4$ . The crystallite size of G1M3, G1M1 and G3M1 were respectively 12, 65 and 23 nm based of the calculation made on using the Debye-Scherrer formula of the 211 plane.

The surface morphology of the bare  $\text{Mn}_3\text{O}_4$  and the nanocomposites G1M1 and G3M1 was investigated using HR-TEM and SAED analyses (Fig. 2). The image formation of the bare  $\text{Mn}_3\text{O}_4$  shows spherical-like particles with an average size of 12 nm (Fig. 2A). The selected-area electron-diffraction pattern (SAED) of the nanoparticles is in harmony with the Hausmannite  $\text{Mn}_3\text{O}_4$  phase and exposes strong ring patterns due to (101), (103), (211) and (220) planes. The spherical like particles were well distributed with a little tendency of forming clusters probably due to increasing the surface free energy of the nanoparticles. The TEM image shown in Fig. 2B for G1M1 reveals the existence of two types of morphological crystals for  $\text{Mn}_3\text{O}_4$  including square and spherical architectures decorating

graphene nanosheets. The square shape indicates an average dimension of 44 nm where the spherical ones reveal a dimension equal 10 nm. The inset figure confirmed the formation of the Hausmannite  $\text{Mn}_3\text{O}_4$  phase *via* the selected area electron diffraction (SAED) pattern and thus exposed visible rings ascribed to 101, 103 and 211 lines. Another diffraction spot in the latter SAED pattern is also recognized and correlated to the 002 facet of graphene, giving a hint about the intimate contact between  $\text{Mn}_3\text{O}_4$  and graphene nanosheets. The TEM image of the G3M1 sample (Fig. 2C) shows polyhedral structures including spherical, regular tetrahedron and rectangular, as illustrated in the high resolution TEM image shown as inset in Fig. 2C. They have an average diameter in the 10–12 nm range. The selected area electron diffraction pattern indicates visible rings that expose lattice fringes 101, 103, 211, 220 and 002 extended from exterior to interior and indexed respectively to Hausmannite  $\text{Mn}_3\text{O}_4$  phase and graphene (002). This pattern indicates the well dispersion of  $\text{Mn}_3\text{O}_4$  nanoarchitectures and its overlaying on graphene and rather emphasizes the strong interaction between them. That high dispersion of  $\text{Mn}_3\text{O}_4$  within the great percentage of graphene sheets (G3M1) induces strong interaction between them and thus governs the particles size enlargement. A criterion about that interaction and consequences thereof concerning the agglomeration prevention of  $\text{Mn}_3\text{O}_4$  nanoparticles as a result of its distribution between graphene nanosheets, is indeed comes through varying the

Fig. 2 TEM images of (A)  $\text{Mn}_3\text{O}_4$  (B) G1M1 (C) G3M1 and (D) G1M3 together with the corresponding magnified HRTEM images and SAED patterns, as insets.

morphology of the parent  $\text{Mn}_3\text{O}_4$  and when it interacts with graphenes. That particle growth inhibition preserves the high-surface-area interface between  $\text{Mn}_3\text{O}_4$  and graphenes. The images of G3M1 (Fig. 2D) indicated SAED pattern typical to all nanocomposites and rather shows spherical and square nano-architectures of dimension 12 nm and 50 nm, respectively.

### 3.2. FTIR and UV-Vis spectroscopy

The FTIR spectra of the synthesized samples are presented in Fig. 3. Apparently RG spectrum indicates small bands at 1710, 1632, 1581, 1415, 1383, 1112 and 1039  $\text{cm}^{-1}$  confirming the presence of residual oxide moieties on its surface. The bands at 1710 and 1632  $\text{cm}^{-1}$  are respectively, assigned to vibrations of C=O stretching<sup>30</sup> and absorbed water molecules.<sup>31</sup> Whereas, the bands at 1415, 1383, 1112 and 1039  $\text{cm}^{-1}$  are assigned to O-H deformation vibrations of tertiary C-OH,<sup>32</sup> bending absorption of carboxyl group,<sup>33</sup> C-OH stretching<sup>34</sup> and C-O stretching vibration of the epoxy groups,<sup>35</sup> respectively. The band at 1580  $\text{cm}^{-1}$  is indicative to the GO reduction since it's correlated to the aromatic C=C skeletal vibrations of unoxidized graphitic carbon.<sup>33-35</sup> On the other hand, the  $\text{Mn}_3\text{O}_4$  spectrum indicates prominent small bands at 1632, 1495, 1383, 1112 and 1039  $\text{cm}^{-1}$  beside bands at 614 and 498  $\text{cm}^{-1}$ . The former bands assigned respectively, to adsorbed water molecules (1632  $\text{cm}^{-1}$ ), OH deformation vibrations (1495  $\text{cm}^{-1}$ ) and C-OH vibrations (1383-1039  $\text{cm}^{-1}$ ). These bands are indicative of the prominent existence of some residual acetate moieties attached to the Mn precursor. The band at 614  $\text{cm}^{-1}$  characteristics of the Mn-O bending mode at tetrahedral sites together with the band at 498  $\text{cm}^{-1}$  correlated to the distortion vibrations of Mn-O in an octahedral position was observed. The G3M1 spectrum exhibits a combination of the bands existed for

RG and  $\text{Mn}_3\text{O}_4$  with revealing a reduction in intensity of the latter when compared with the bare  $\text{Mn}_3\text{O}_4$ . This gives a hint about the strong interaction between the moieties forming the G3M1 sample. Furthermore, shifting the Mn–O vibrations in the latter into longer wavenumbers ( $624$  and  $524\text{ cm}^{-1}$ ) compared to the bare  $\text{Mn}_3\text{O}_4$  ( $613$ ,  $490\text{ cm}^{-1}$ ) reflects considerably the strong interaction exhibited between GO and  $\text{Mn}_3\text{O}_4$ . It is shown that the band area ratio of tetrahedral/octahedral in G3M1 is higher than that in the bare, which showed the revers behaviour. In case of G1M1, the bands are somehow typical to those seen on G3M1 with slight shifting the low IR bands seen at  $624$  and  $524\text{ cm}^{-1}$ ; in G3M1, into  $631$  and  $527\text{ cm}^{-1}$ , respectively. A new tiny band at  $405\text{ cm}^{-1}$  is developed. This latter band is more close to Mn–O vibrations of  $\text{MnO}_6$  shown in  $\alpha\text{-MnO}_2$  species,<sup>36</sup> confirming the previously observed XRD results of G1M1. Interestingly, the G1M1 sample presented equal intensity ratio for tetrahedral and octahedral band structure. It appears also that the band at  $1627\text{ cm}^{-1}$  undergoes splitting in G1M1 and G3M1 samples to give doublet and thus exposes in addition a band at  $1580\text{ cm}^{-1}$ . This gives a hint about the reduction of GO at such  $\text{Mn}_3\text{O}_4$  loadings. However, increasing the ratio of  $\text{Mn}_3\text{O}_4$  to GO (as in G1M3) has substantiated the intensities of the Mn–O bands, those exhibited at  $610$  and  $488\text{ cm}^{-1}$  together with evolution of small bands at  $444$  and  $400\text{ cm}^{-1}$  due to  $\text{Mn}^{3+}$  in octahedral sites.<sup>37,38</sup> This highlights that increasing the concentration of  $\text{Mn}_3\text{O}_4$  species (G1M3) indicates not only different geometrical structural of  $\text{Mn}_3\text{O}_4$  but also specifies lower strength compared to other nanocomposites. Exposing the tetrahedral structure in G3M1 exceeding that of the thermodynamically favourable octahedral one may substantiate the high cationic mobility of  $\text{Mn}_3\text{O}_4$ , its superior electronic properties and its decreased particles sizes. In G1M3, the bands in the C–OH region have been substantiated ( $1050\text{--}1400\text{ cm}^{-1}$ ) together with OH stretching band at  $3420\text{ cm}^{-1}$  with disappearing that at  $1580\text{ cm}^{-1}$ . This reflects the oxidation effect of  $\text{Mn}_3\text{O}_4$  on RGO at such high loadings of  $\text{Mn}_3\text{O}_4$  (G1M3). Existence of bands correlated to  $\text{MnO}_2$  in G1M1 and  $\text{Mn}_2\text{O}_3$  in G1M3 might reflect the thermodynamic differences in surface energies that under wet conditions was amenable to expose  $\text{MnO}_2$  and  $\text{Mn}_2\text{O}_3$  moieties together with the most prominent  $\text{Mn}_3\text{O}_4$  mostly obtained under dry conditions.<sup>39,40</sup> This has been ascertained *via* increasing the broadness of the OH stretching band as well as C–OH ones in G1M3. The absence of the more oxidized  $\text{Mn}_2\text{O}_3$  species in the XRD pattern of G1M1 comprehends its small amounts and indeed raises the sensitivity of the FTIR technique. However, exceeding the XRD crystallinity of  $\text{Mn}_3\text{O}_4$  peaks in G1M1 relative to pure  $\text{Mn}_3\text{O}_4$  lines might indicate overlaying of other phase(s).

The UV-Vis absorption spectra of pure  $\text{Mn}_3\text{O}_4$  and GM hybrids are compared in Fig. 4. The  $\text{Mn}_3\text{O}_4$  spectrum shows a strong band at 210 nm due to the allowed  $\text{O}_2^- \rightarrow \text{Mn}^{2+}$  and/or  $\text{O}_2^- \rightarrow \text{Mn}^{3+}$  charge transfer transitions with almost no absorption in the visible light region. In comparison with the latter sample, the nanocomposite samples show strong absorption in the visible light region. The nanocomposites exhibit a band at 230 nm; besides the mentioned one at 210 nm, due to  $\pi-\pi^*$  transitions of the aromatic C=C bonds in

**Fig. 3** FTIR spectra of RGO,  $\text{Mn}_3\text{O}_4$ , G3M1, G1M1 and G1M3.

Fig. 4 UV-Vis absorption spectra of RGO, Mn<sub>3</sub>O<sub>4</sub>, G3M1, G1M1 and G1M3, and their corresponding plots of  $(\alpha h\nu)^2$  versus  $(h\nu)$  for energy bandgap ( $E_g$ ) determination.

graphene structure. The nanocomposites containing graphene that showed absorption enhancement in the whole region were in the order; G3M1 > G1M1 > G1M3. This indeed maximized the effect of graphene appropriate percentages relative to Mn<sub>3</sub>O<sub>4</sub> along with the color changes from black to grey. This was in concordance with the reported results of other GR-including nanocomposites.<sup>41</sup> The electronic absorption spectra of the nanocomposites also show broad bands from 390 to 530 nm in G1M3 where it extends into 600 nm in G1M1 and G3M1. This indeed is correlated to d-d crystal field transitions on octahedral Mn<sup>3+</sup> species<sup>42</sup> and rather proposes the strong interaction between the moieties forming the composite. This is expected to increase the harvesting capability of the nanocomposites to have a great impact on their photocatalytic performances probably in the same sequence under visible illumination. The band gap energy of the samples is calculated *via* using the equation:

$$\alpha h\nu = A(h\nu - E_g)^n, \quad (1)$$

where  $\nu$ ,  $\alpha$ ,  $E_g$  and  $A$  is respectively light frequency, absorption coefficient, band-gap energy and a constant.<sup>43</sup> The part  $n$  is a constant fits with 1/2 to comprehend that the optical

transition is of a direct allowed type.<sup>44</sup> Accordingly, the estimated band-gap energies of G, Mn<sub>3</sub>O<sub>4</sub>, G1M1, G3M1 and G1M3 based on the latter equation are 1.39 eV, 3.1 eV, 1.44 eV, 1.41 eV and 2.05 eV, respectively (Fig. 4 inset). All the GM nanocomposite samples have band gap energies in the region between those of graphene and Mn<sub>3</sub>O<sub>4</sub> accomplishing the strong interaction devoted between them.

### 3.3. Raman spectroscopy

To gain more information about the structure of the graphene sheets and its interaction with Mn<sub>3</sub>O<sub>4</sub>, Raman spectra were recorded (Fig. 5). The Raman spectrum of the bare Mn<sub>3</sub>O<sub>4</sub> shows a strong peak at 641 cm<sup>-1</sup> ascribed to the A<sub>1g</sub> mode correlated to the oxygen vibrations in the MnO<sub>6</sub> unit.<sup>45</sup> The Raman spectrum of G1M1 displays the G peak at 1570 cm<sup>-1</sup> correlated to the ordered sp<sup>2</sup> bonded carbon together with the D peak at 1347 cm<sup>-1</sup> due to edges or disordered layers.<sup>46</sup> The small peaks in the margin 200–400 cm<sup>-1</sup> ascribed to Mn<sub>3</sub>O<sub>4</sub> modes<sup>47</sup> were intensified in the G1M1 spectrum compared to the pristine Mn<sub>3</sub>O<sub>4</sub> to comprehend the proposed weak interaction between the moieties forming G1M1. Conversely, the G3M1 spectrum illustrates in addition to D and G peaks a very small peak due to

Fig. 5 Raman spectra of  $\text{Mn}_3\text{O}_4$ , G3M1, G1M1 and G1M3.

the free  $\text{Mn}_3\text{O}_4$  ( $641\text{ cm}^{-1}$ ) that constitutes 1/5 of its intensity in G1M1 and 1/4 to that in the bare  $\text{Mn}_3\text{O}_4$ . Taking into consideration the Mn to G ratios, one easily confirms that the interaction between  $\text{Mn}_3\text{O}_4$  with graphene was more intense in G3M1 compared to the other nanocomposites. Shifting the G band from  $1570\text{ cm}^{-1}$  in G1M1 and G1M3 to  $1580\text{ cm}^{-1}$  in G3M1 confirms the devoted strong interaction of  $\text{Mn}_3\text{O}_4$  with graphene and rather announces lowering of graphene layer thickness in the latter sample than those in the former.<sup>47,48</sup> Both of the nanocomposites show the 2D band; characteristics of two phonon lattice vibration process,<sup>48</sup> of the same shape and position extending from  $2550$  to  $2850\text{ cm}^{-1}$ . Accordingly, the synthesized graphene is multilayered given that D in RG is very strong than the 2D. The intensity ratio of D and G peaks ( $I_D/I_G$ ) offers a precise measure of the disorder and crystallite size of the graphitic layers. The  $I_D/I_G$  intensity ratio of RG (1.34) exceeded those of G3M1 (1.31), G1M1 (1.26) and G1M3 (1.12) confirming a relative lower density of imperfection in RG following the  $\text{Mn}_3\text{O}_4$  incorporation.

### 3.4. Surface texturing

Fig. S1† presented the  $\text{N}_2$  adsorption–desorption isotherms of some synthesized samples in conjunction with their pore size distribution (PSD) curves. They demonstrate type II isotherm with H3 hysteresis loops characterizing aggregates of plate-like or slit-shaped pores.<sup>49</sup> Incorporation of  $\text{Mn}_3\text{O}_4$  into RG decreases the  $S_{\text{BET}}$  value from  $142.6\text{ m}^2\text{ g}^{-1}$ ; in pristine RG, into  $116\text{ m}^2\text{ g}^{-1}$  in G1M1 and  $105.6\text{ m}^2\text{ g}^{-1}$  in G3M1. The hysteresis loops of the samples close at  $P/P_0$  values of 0.46, 0.46 and 0.45 for RG, G1M1 and G3M1, respectively. This signifies the presence of alike large pores in all the samples except RG that shows another hysteresis closes at  $P/P_0 = 0.84$ , representing the involvement of micropores as well. That hysteresis is disappeared following  $\text{Mn}_3\text{O}_4$  involvement illustrating the well incorporation of the latter between RG sheets. As a confirmation

for the mentioned order in surface area, the pore volume values indicate alike trend *via* giving values equal  $0.1124$ ,  $0.0912$  and  $0.0818\text{ cm}^3\text{ g}^{-1}$  for RG, G1M1 and G3M1, respectively. This elaborates that the pore volumes are reduced where the pore radii are only narrowed for the G1M1 sample ( $27.67\text{ Å}$ ) and it was reluctant in G3M1 ( $28.9\text{ Å}$ ). The pore size distribution (PSD) curves of all the samples have shown the existence of trimodal type of pores ( $2\text{ nm}$ ,  $2.9\text{ nm}$  and  $4.2\text{ nm}$ ) all occur in the low margin of mesopores. The relative intensity of the peaks; correspond to different types of the pores, suffered a decrease in the order; G3M1 > G1M1 > RG. This elaborates the well inclusion of  $\text{Mn}_3\text{O}_4$  between RGO sheets in G3M1 and G1M1 samples accomplishing the strong interaction between the moieties forming these samples. Decreasing the pore volume of the G3M1 sample compared to rest of samples while keeping its pore radius unaffected reflects the dispersion of  $\text{Mn}_3\text{O}_4$  deep between RG sheets.

### 3.5. Photocatalytic degradation of the MB dye

The photocatalytic degradation of as-synthesized nanocomposites RG– $\text{Mn}_3\text{O}_4$  (G3M1, G1M1 and G1M3) was studied *via* using the methylene blue (MB) dye at a concentration of  $20\text{ ppm}$  and at room temperature. These samples were initially left for  $60\text{ min}$  in MB solutions before irradiation for ascertaining equilibrium adsorption. Upon visible light irradiation ( $88\text{ W}$ ,  $\lambda > 420\text{ nm}$ ), the G1M3 sample did not exhibit any activity apart from that related to the dye absorption and comprised of  $30\%$  (Fig. 6). The photocatalyst G1M1 exhibits MB degradation equal  $92\%$ , showing fast oxidative decomposition upon increasing the RG ratio. It seems also that the RG ratio affected the adsorption process to reach  $52\%$  in this latter sample. A further increase in the RG ratio as in the G3M1 sample has indicated an efficient MB degradation *via* achieving  $100\%$  in

Fig. 6 Photocatalytic degradation of the MB dye by  $\text{Mn}_3\text{O}_4$ , G3M1, G1M1 and G1M3 photocatalysts under visible light irradiation: reaction conditions: (lamp power =  $88\text{ W}$ , filter  $\lambda = 420\text{ nm}$ , catalyst weight  $100\text{ mg}$ , dye conc.  $20\text{ ppm}$ ). Insets are the kinetic fits for MB degradation *via* the as-synthesized photocatalysts.

only 60 min. Although the latter catalyst contains the highest RG ratio, it indicates low absorption percentages under dark condition comprised of 24%. It is necessarily declaring that this reaction proceeds without any oxidizing agent unlike those devoted by Chunxiang He *et al.*<sup>9</sup> and Shaobin Wang *et al.*<sup>14</sup> whom used H<sub>2</sub>O<sub>2</sub> and peroxymonosulfate, respectively with the composites of Mn<sub>3</sub>O<sub>4</sub>/GO. This reveals an increase of our samples oxidizability under photo-irradiation. On the other hand, the bare Mn<sub>3</sub>O<sub>4</sub> indicates dark adsorption comprised of 30% that continues to give 58% degradation under visible light irradiation after 120 min. Accordingly, it seems that the synergy between Mn<sub>3</sub>O<sub>4</sub> and RG plays a significant role in the dye degradation *via* photocatalysis. Concisely, the RG/Mn<sub>3</sub>O<sub>4</sub> ratio and specifically G3M1 manipulates the efficient decomposition of the MB dye since the individual components showed lower catalytic activity than the nanocomposites. Plotting  $\ln C_0/C$  vs. time (min) indicates straight lines (see the inset in Fig. 6) with slopes indicative to the reaction rate constants. These lines indicate that the oxidation reaction follows pseudo-first order rate kinetics. The rate constant values that performed at 298 K were in the order: G3M1 (0.0791 min<sup>-1</sup>) > G1M1 (0.0428 min<sup>-1</sup>) > Mn<sub>3</sub>O<sub>4</sub> (0.0114 min<sup>-1</sup>) > G1M3 (0.0005 min<sup>-1</sup>). Since, the nanocomposite G3M1 presented the most promising photo-activity result, it has been used for performing further reactions. At certain reaction intervals, the UV-Vis absorption spectra of the MB dye were undertaken while tracing its photocatalytic degradation using the nanocomposite G3M1. As shown in Fig. S2,† two absorption peaks at 615 and 664 nm are observed characterizing the MB typical peaks.<sup>50</sup> These absorption peaks diminish with time and the solution turns colourless gradually within 60 min irradiation time. The TOC% of the same sample taken during the 60 min reaction time; inset in Fig. S2,† indicates 60% elemental carbon representing the photodegradation ratio of the dye organic carbons. However, the difference between  $C/C_0$  and TOC% values; typical of 40%, are mostly correlated to the presence of non-degradable intermediates produced during the photo-degradation process. However, extending the time into 120 min has accomplished the 100% TOC degradation verifying the complete transformation of organic carbons into elemental carbons.

To shed an idea about the reactive species could be involved in the oxidation process, some recognized scavengers were added to investigate their role on the reaction rate. Accordingly, the effects of the addition of benzoquinone; BQ, isopropanol; IPA, triethanolamine; TEOA, and carbon tetrachloride; CCl<sub>4</sub>, on the catalytic oxidation of the MB dye over the photocatalyst G3M1 have been investigated under identical experimental conditions (Fig. 7). It has been shown that the reaction rate was relatively retained upon using BQ reflecting the small effect of the 'O<sub>2</sub><sup>-</sup> species. The experiment with IPA has indicated a higher decrease than that evoked *via* BQ, proposing the influential effect of 'OH. A significant decrease was obtained for the MB oxidation following the addition of TEOA and CCl<sub>4</sub> comprehending the efficacy of both holes and electrons in the MB oxidation mechanism. This suggests that the intimate contact between Mn<sub>3</sub>O<sub>4</sub> and graphene in G3M1; as confirmed from HRTEM-SAED, Raman and FTIR, is beneficial for the

Fig. 7 Effect of reactive scavengers on the degradation activity of the G3M1 photocatalyst towards MB under visible light irradiation and under the mentioned reaction conditions.

production of the main reactive species 'OH resulted due to the visible light absorption. Indeed, the produced photogenerated holes from the VB of Mn<sub>3</sub>O<sub>4</sub> were responsible for creating the latter reactive species as a consequent of its interaction with OH<sup>-</sup>/H<sub>2</sub>O species. Hypothetically, based on conduction and valence band edge energy calculation,<sup>51</sup> the photoexcited electrons in the CB of Mn<sub>3</sub>O<sub>4</sub> in G3M1 can reduce O<sub>2</sub> to 'O<sub>2</sub><sup>-</sup> since the CB edge potential (of -4.01 eV vs. NHE) is more negative compared to the standard redox potentials of E<sub>Θ</sub> (O<sub>2</sub>/'O<sub>2</sub><sup>-</sup>) (-0.33 eV vs. NHE). However, the scavenger study indicates the negligible effect of the latter reactive species. Compatibly, 'OH can be created by 'O<sub>2</sub><sup>-</sup> rather than h<sup>+</sup> in the VB of Mn<sub>3</sub>O<sub>4</sub> because of the more negative Mn<sub>3</sub>O<sub>4</sub> VB potential (-0.2.6 eV) relative to the standard redox potential of OH<sup>-</sup>/'OH (E<sub>Θ</sub> = 2.4 eV).<sup>49,52</sup> Hence, the generation of 'OH and the involvement of 'O<sub>2</sub><sup>-</sup> in the synthesis of the latter can be proposed *via* the following equations.

Based on the presented results, the photocatalytic mechanism can be proposed as follows (Scheme 1). In the Mn<sub>3</sub>O<sub>4</sub>/RG composites, Mn<sub>3</sub>O<sub>4</sub> attached on the surface of RG produces electron-hole pairs as a result of photons absorption when exposed to visible light irradiation. Effective separation of the charges is attained given that RG acts as an effective scavenger for the produced electrons. Herein, electrons absorbed by RG

Scheme 1

can react with the adsorbed  $O_2$  to yield  $\cdot O_2^-$  that by its turn transferred into  $\cdot OH$  together with the  $OH^-$  ions dedicated as well to produce  $\cdot OH$ . Also,  $\cdot OH$  can be obtained *via* direct water oxidation or reduction of  $H_2O_2$ . Investigation that the latter moieties is *in situ* formed is traced by measuring the light absorption of the titanate-hydrogen peroxide compound.<sup>52</sup> Accordingly,  $\cdot OH$  moieties compile their definite effects in effective MB dye oxidation. Nevertheless, one must bear in mind that our RG is functionalized by residual oxygen moieties on its surface; in conformity with  $E_g$  data ascertaining its semiconducting property, enabling it to take part in the photoreaction products. Accordingly, the photo-generated holes could be capture by not only the lattice oxygen in  $Mn_3O_4$  but also those on RG sheets to form  $\cdot OH$  active species. On the other hand, the photogenerated  $h^+$  in the VB is also amenable for generating  $\cdot OH$  *via* the reaction with  $H_2O$ .

In addition, it is very important to confirm that the photodegradation obtained for the nanocomposites is consistent with the values estimated from incident photon to current efficiency (IPCE) spectra (Fig. 8). This is because photodegradation is entirely dependent on the incident light and the consequences thereof concerning the impinging photons. As shown in Fig. 8, the G3M1 electrode possessed the highest IPCE values over the wide range from 350 to 750 nm compared to rest of the samples. This result was in harmony with the devoted UV-Vis absorption spectra (Fig. 4) in which G3M1 has indicated the highest absorption throughout all the studied range (200–800 nm) and rather it indicates the lowest  $E_g$  value (1.41 eV). Increasing IPCE of the G3M1 electrode in the wavelength range of 600–700 nm could also be due to increasing the absorption capacity of the MB dye (Fig. 8). Increasing the IPCE of same sample in the narrow wavelength range of 470–490 nm; in which the MB dye has a low absorption for incident light, reflects that this promotion is directly correlated to the phenomenon of light scattering. This result further confirmed the superior light absorption and scattering properties of the G3M1 electrode in the long wavelength region. This explains the higher efficiency of G3M1 in photodegrading the MB dye compared to rest of the

catalysts. Exposing the tetrahedral structure of  $Mn_3O_4$  in G3M1 than the octahedral one; as deduced from FTIR results, may substantiate the facile mobility of  $Mn_3O_4$  in enhancing the photocatalysis of this specific sample together with its decreased particles size.

It's of important notifying that at the 25 wt% of RGO loading (as in G1M3), no photoactivity is exhibited where after increasing the weight ratio of RGO compared to Mn a superior photoactivity is attained. This is due to at the former ratio, an oxidized GO is obtained due to the excessive amounts of  $Mn_3O_4$  (75 wt%) and this prohibits the facile electron transfer due to its scavenger throughout oxygen functional groups leading to high loss of charges. Conversely, increasing the ratio into 75% graphene (as in G3M1) reduces tremendously the residual oxygen, as revealed from IR results, and thus acts as an electron acceptor/donor capable of performing magnificent role in the dye degradation. Convincingly, the strong adhering of  $Mn_3O_4$  into RG; which retained the particles size of the former at  $\sim 12$  nm, has shown exceptional optical and texturing properties those in turn caused

Fig. 8 Incident-photon-conversion efficiencies (IPCE%) of  $Mn_3O_4$ , G3M1, G1M1 and G1M3.

Fig. 9 The recycle test during degradation of MB using G3M1 under visible light illumination.

high oxidative decomposition for the MB dye in the absence any oxidants unlike many comparable nanocomposites.<sup>9,14,25</sup>

The stability and recyclability of the G3M1 nanocomposite was evaluated by successive tests for the MB decolorization (Fig. 9). It is established that the G3M1 photocatalyst can work at least four cycles without noticeable loss in the catalytic activity, demonstrating the long-term durability of this nanocomposite. Whereas, the fifth run indicates retaining of the 85% of the catalyst activity proposing an excellent stability while reusing for 300 min.

### 3.6. Microwave absorption of $\text{Mn}_3\text{O}_4$ /graphene for MB degradation

Fig. 10 shows the normalized degradation curves of MB treated in the microwave reactor; for 30 min at 373 K and under 1 atm pressure, with the nanocomposite catalysts as well as with the free  $\text{Mn}_3\text{O}_4$  catalyst. During the microwave treatment, the nanocomposite G3M1 catalyst indicates the best MB degradation performance by signifying 100% color removal. This only takes 10 min compared to 60 min in the photocatalytic reaction performed for the same sample. Accordingly, the consequence of the studied nanocomposites was in the order; G3M1 > G > G1M1 > Mn > G1M3. These results maximized the role of the synergistic effects between  $\text{Mn}_3\text{O}_4$  and graphene at high percentages of the latter (G3M1) since, it shows higher degradation percentages than pristine  $\text{Mn}_3\text{O}_4$  and graphene nano-architectures. It was found that the G1M1 catalyst exhibits a microwave catalytic activity comprised of 70% degradation whereas that of G1M3 indicates 40%, both in 30 min irradiation time. The microwave degradation of MB by a direct microwave irradiation in the absence of a catalyst was almost zero. Additionally, to exclude that the degradation has nothing to do with the sample heating, the nanocomposites were heated to 373 K with the MB solution for 1 h away from microwave irradiations to comprehend zero degradation. Whereas, the microwave degradation of MB in presence of nanocomposites was found to follow pseudo-first-order decay kinetics.<sup>53</sup> Based on the Langmuir-Hinshelwood model, the estimated reaction rate (Fig. 10

Fig. 10 Microwave degradation of MB dye by  $\text{Mn}_3\text{O}_4$ , RGO, G3M1, G1M1 and G1M3 nanocomposites: reaction conditions: (temp. = 373 K, catalyst weight 100 mg, dye conc. 20 ppm, 800 W, 2.45 GHz). Insets are the kinetic fits of MB degradation via the as-synthesized nanocomposites.

inset) was in the order G3M1 ( $0.287 \text{ min}^{-1}$ ) > G ( $0.085 \text{ min}^{-1}$ ) > G1M1 ( $0.045 \text{ min}^{-1}$ ) > Mn ( $0.026 \text{ min}^{-1}$ ) > G1M3 ( $0.016 \text{ min}^{-1}$ ) (Fig. 11). It's interesting notifying that the activity of microwave irradiation of G3M1 while degrading MB exceeded that obtained via photocatalysis by 3.5 times.

The scavenger studies for detecting the reactive species could be responsible for MB degradation while employing the microwave absorption property of nanocomposites were performed (Fig. 11). Notably, when TEOA and BQ used, the degradation efficiency is overall similar to that of the blank without scavengers and thus nullifies the influence of holes and  $\text{O}_2^-$  species. Whereas, upon using IPA and  $\text{CCl}_4$  a significant decrease in activity is perceived relative to that of the blank implying that  $\cdot\text{OH}$  and electrons are the major reactive species for G3M1. This advocates that the coupling effect between microwave and the active  $\cdot\text{OH}$  species on  $\text{Mn}_3\text{O}_4$  incorporated

Fig. 11 Effect of reactive scavengers on the degradation activity of the G3M1 nanocomposite towards MB under microwave irradiation and under the mentioned reaction conditions.

graphenes is participated in the MB degradation. It has been notified that  $\cdot\text{OH}$  is produced considerably by  $h^+$  in the VB of  $\text{Mn}_3\text{O}_4/\text{graphene}$  (G3M1) owing to its more negative potential than the standard redox potential of  $\text{OH}/\cdot\text{OH}$  ( $E^\ominus = 2.4 \text{ eV}$ ).<sup>53</sup> The violent motion of polar materials; exerted due to collisions between reactant molecules due to microwave irradiation, can compete with the catalytic reactive species to accelerate degradation of the MB dye.

To configure the role of electrons during the microwave MB degradation performance; as committed from the trapping experiments, the electrical conductivity of as-synthesized nanocomposites as well as the bare  $\text{Mn}_3\text{O}_4$  was measured at temperature range from room temperature to 373 K (Fig. 12). The electrical conductivity values were found to decrease from  $0.033 \Omega^{-1} \text{ cm}^{-1}$ ,  $0.028 \Omega^{-1} \text{ cm}^{-1}$ ,  $0.002 \Omega^{-1} \text{ cm}^{-1}$  and  $6.0 \times 10^{-9} \Omega^{-1} \text{ cm}^{-1}$  for G3M1, G1M1, G1M3, and  $\text{Mn}_3\text{O}_4$ , respectively. This indicates that the combination of graphene with  $\text{Mn}_3\text{O}_4$  nanocomposites can strongly increase the electronic conductivity compared to the bare  $\text{Mn}_3\text{O}_4$ . It also indicates the potentiality of graphene specifically in the nanocomposite G3M1, reflecting the synergism between the components forming this composite. Based on the high absorptivity of carbon containing materials including graphenes to microwave, hot-spots are formed to act as oxidation centres for the pollutants oxidation.<sup>53</sup> That selective heating stimulates molecular rotation causing a decrease in the activation energy (see Fig. 10).

Since microwave assists the rise of temperature of the samples thus, an increase in the number of carriers and lattice vibrations is expected to be obtained.<sup>52</sup> Indeed, increasing the temperature increases the number of carriers and consequently it leads to conductivity elevation (inset in Fig. 12). Scheme 1 also illustrates the effect of  $\cdot\text{OH}$  and electrons evoked while microwave irradiation on the MB degradation. Of particular interest, although the nanocomposites G1M1 and G1M3; of alike thickness, show the presence of small amounts of  $\text{MnO}_2$  and  $\text{Mn}_2\text{O}_3$

species; as devoted from XRD and IR results, they still indicate lower conductivity values than G3M1. This declares that the geometric defects obtained in G1M1 and G1M3 samples such as dislocations and grain boundaries<sup>54</sup> are great; as exactly devoted from surface properties and TEM results. Consequently, such grain boundaries in graphene can disrupt the electron transfer and thus being trapped causing the depletion in charge carriers. The strong interaction devoted between  $\text{Mn}_3\text{O}_4$  and graphene in G3M1; confirmed *via* IR, Raman, TEM-SAED and surface texturing data, minimizes the presence of discrete boundaries, structural disorders and surface imperfections between the moieties forming this sample. On the other hand, the lattice vibrations create phonons and thus an expected interaction between electron-phonon can be perceived.<sup>54</sup> Undoubtedly, G1M1 and G1M3 must have shown more charge carriers than G3M1 due to evoking  $\text{Mn}^{4+}$  and  $\text{Mn}^{3+}$  species on their surfaces; as depicted *via* XRD and IR results. However, the devoted decrease in their conductivities explains the possibility of hampering the electrons by phonons and as a result affecting the oscillation mode occurs in their lattice structures influencing their conductivities (Fig. 12).

Increasing the microwave catalytic activity of G3M1 was due to enhancement of the microwave absorption as a result of the change occurring in dielectric constant and dielectric loss caused by the addition of  $\text{Mn}_3\text{O}_4$  to graphene. Under the alternating electromagnetic field, interfacial and space-charge polarization can easily be formed at the interface of  $\text{Mn}_3\text{O}_4/\text{graphene}$  and also due to the conducting nature of graphene and the dielectric nature of  $\text{Mn}_3\text{O}_4$ . Fig. 13a shows that the nanocomposites dielectric constant ( $\epsilon''$ ); inferred to the storage ability of electric current, decrease continuously with increasing frequencies to be in the order;  $\text{G3M1} > \text{G1M1} > \text{G1M3} > \text{Mn}$ . The monotonous decline in dielectric constants on increasing frequencies may be attributed to the combined contribution caused by electronic, ionic, and interfacial polarization.<sup>58</sup> The observed dielectric distribution at low frequencies can be explained on the basis of the Maxwell-Wagner theory of interfacial polarization<sup>59</sup> by which the dielectric structure of the composite consists of two layers. The number one layer stands for a large number of grains that act as conducting layer at lower frequencies and the other layer consists of grain boundaries that act as highly resistive medium at higher frequencies. At low frequencies, the polarization process in composites of high percentages of  $\text{Mn}_3\text{O}_4$  (G1M3) can be described as a local displacement of electrons *via* hopping mechanism between  $\text{Mn}^{3+}$  and  $\text{Mn}^{4+}$  and an orientation of electric dipole in the direction of the applied field. Nevertheless, the monitored decrease in the latter sample dielectric constant is in part due to the presence of residual oxygenated functional groups; depicted *via* IR results. That presumably lessens the direct contact between graphene nanosheets and thus facilitates the electron transfer through oxygen functional groups leading to high dielectric loss (Fig. 13b). Increasing the microwave absorption property of G3M1 could also be caused by dielectric relaxation and interfacial scattering.<sup>55,56</sup> The dielectric relaxation and polarization was mainly induced by interfacial multipoles, which took place along the boundaries between graphene

Fig. 12 Conductivity results of  $\text{Mn}_3\text{O}_4$ , G3M1, G1M1 and G1M3 samples measured at room temperature and at 373 K. Inset is the  $\sigma$  vs.  $T$  for exploring the effect of increasing temperature on the conductivity.

Fig. 13 The dielectric constant (a) and dielectric loss (b) of  $\text{Mn}_3\text{O}_4$ , G3M1, G1M1 and G1M3 and their counterparts ( $a_1$ ) and ( $b_1$ ) as a function of frequency change in the margin from 1.0 Hz to 100 kHz.

sheets and  $\text{Mn}_3\text{O}_4$  moieties.<sup>57,58</sup> It has been documented that charges would transfer throughout the interface in a metal graphene heteroarchitecture due to their different work function and thus an electron transfer from  $\text{Mn}_3\text{O}_4$  to graphene can be anticipated. Accordingly, a charge transfer process can rationally be assumed at the interface of G3M1, leading to the introduction of the free carriers into graphene sheets. The latter carriers would vibrate with the microwave motivation giving rise to electric polarization in graphene and thus increase the value of  $\epsilon'$  in G3M1 compared to rest of the composites (Fig. 13a). Furthermore,  $\epsilon'$  of all nanocomposites decreases with increasing frequency (Fig. 13a<sub>1</sub>) owing to the relaxation of polarization and thus shows a dielectric dispersion. The small-size particles (12 nm) observed in G3M1 involves large number of particles per unit volume resulting in an increase of the dipole moment per unit volume and thus induces the highest dielectric constant. In the meantime, the motion of the introduced free carriers would attenuate the microwave energy, resulting in the enhancement of the dielectric loss  $\epsilon''$  (Fig. 13b). Attenuation of dielectric loss with increasing frequencies was also attained; as seen in the corresponding Fig. 13b<sub>1</sub>. Diminishing the dielectric constant with increasing frequency is dedicated to the polarization decrease of the dipoles when the electric field propagates with high frequencies. Interestingly, the G3M1 sample has indicated the lowest decrease in dielectric

loss with increasing frequency between all samples. This latter behaviour is explained on the basis that in dielectric nanostructured materials, interfaces are produced with large volume fractions involving great number of defects such as vacancies, dangling bonds and microporosities.<sup>58</sup> These can cause a change in negative and positive space charge distribution at the interfaces. Such space charges when subjected to an electric field, they trapped by defects to form lots of dipole moments. On the other hand, these dipole moments at low frequencies follow the change of the electric field<sup>59</sup> and thus both the dielectric loss and the dielectric constant display high values.

The dielectric properties of the composites are usually correlated to the surface morphology of reduced graphene nanosheets, since it increases as the graphene ratio increase (Fig. 13a and b). Accordingly, the random distribution of the conserved  $\text{sp}^2$  and distorted  $\text{sp}^3$  carbons decorated by various oxygen containing functional groups can be anticipated.<sup>60</sup> Such distribution in RGO works as a nanocapacitor electrode separated by the  $\text{Mn}_3\text{O}_4$  dielectric material. Thus, the revealed considerable improvement in dielectric constant can be attributed to the formation of huge number of nanocapacitors inside the composite.<sup>61</sup> This is believed to originate due to the presence of residual oxygenated functional groups that apparently lessen the direct contact between graphene nanosheets.<sup>62</sup> Consequently, the large capacitance caused by each

nanocapacitor results in a noticeably high local electric field. An environment is afterwards created which is conducive for migration and accumulation of charge carriers at the RGO/Mn<sub>3</sub>O<sub>4</sub> interface. That interfacial polarization named Maxwell–Wagner effect is considered to be responsible for the large dielectric constant at low frequency region.<sup>63</sup> Conversely, the escape current is principally responsible for the high dielectric loss in nanocomposites, as validated in G1M1 and G1M3. This explains that oxygenated functional groups on RGO are not as an insulating layer or intrinsic barriers that limits the current leakage<sup>64</sup> but facilitates the electron transfer through oxygen functional group leading to high dielectric loss.

## 4. Conclusions

The polyhedral nanoarchitecture graphene/Mn<sub>3</sub>O<sub>4</sub> formed at the ratio of G3M1 has shown fascinating photocatalytic performances; under visible light illumination without any oxidants, and microwave irradiation for the purpose of the MB degradation. The experimental results of this type of smart material evokes some important factors by which the enhancement was revealed such as (i) high optical properties explained *via* exceeding the visible light absorption of the sample in the 400–800 nm region as well as increasing the IPCE% value (ii) the devoted strong interaction between the moieties forming G3M1 and the consequence thereof concerning the decrease in  $E_g$  as well as the delay in the charges recombination (iii) increasing the conductivity of this sample at room temperature (*i.e.* indicative to photocatalysis) and rather its enhancement at 373 K (*i.e.* indicative to microwave irradiation) (iv) the superior increase in the dielectric constant at the low frequency margin, at which microwave absorption takes place, explained the extraordinary photocatalytic MB degradation. The excellent microwave absorption seen in G3M1 was attributed to the charge transfer at the latter nanocomposite interface as well as the interfacial polarization that well explained in view of the Maxwell–Wagner effect.
