A perspective on renewable production of amino acids from biomass through the chemocatalytic method

Maofeng Ding,^a Song Song ^{*a,b} and Xingang Li ^{*a,b}

Amino acids are an important class of fine chemicals that contain both amine groups and carboxyl groups, which are commonly used in food, medicine, and cosmetics. The conventional methods for amino acid synthesis, including the Strecker synthesis, enzymatic synthesis, and fermentation, suffer from highly toxic cyanides, non-renewable resources, enzyme instability, and high energy consumption. The development of environmentally friendly technologies for amino acid synthesis remains a formidable challenge. Biomass is the most abundant renewable resource on Earth and serves as an ideal candidate for the production of valuable chemicals and liquid fuels. This perspective highlights the potential of amino acid synthesis from biomass through the chemocatalytic method, including the catalytic conversion of biomass-derived oxygen-containing feedstocks to amino acids by introducing N-functional groups, as well as the catalytic synthesis of amino acids with chitin-derived nitrogen-containing feedstocks as starting materials. Finally, a perspective on critical challenges and future opportunities for amino acid synthesis through the chemocatalytic method is presented.

1 Introduction

Amino acids are the building blocks of proteins, which are widely used in the food and pharmaceutical industries.¹ The global market for amino acids is \$26.55 billion in 2022 and is expected to reach \$57.58 billion by 2032.² This increasing demand necessitates low carbon and highly efficient technologies for amino acid synthesis to meet increasingly stringent environmental quality standards in the chemical industry. Maofeng Ding

Maofeng Ding graduated from the South China University of Technology with a Bachelor's degree in 2021. Later, he joined the research group of Prof. Xingang Li and earned a Master's degree at Tianjin University. His current research interests mainly focus on the photocatalytic conversion of biomass to high-value nitrogen-containing chemicals.

Song Song

Song Song is an Associate Professor at the School of Chemical Engineering & Technology of Tianjin University. He received his Ph.D. under the supervision of Prof. Najia Guan and Prof. Landong Li from Nankai University in 2017. From 2017 to 2020, he worked as a research fellow in Prof. Ning Yan's group at the National University of Singapore. He joined Tianjin University as an Associate Professor in August 2020. His research interests include the thermo/photo-catalytic conversion of biomass to valuable chemicals.

current methods for the production of amino acids mainly include chemical and biological processes. The Strecker synthesis is a well-known chemical method for the production of α -amino acids. However, it utilizes highly toxic cyanides as nitrogen sources and non-renewable aldehydes as substrates. Moreover, an additional step for optical resolution of DL-amino acids is inevitable.^{3,4} The industrial production of amino acids mainly depends on the biological fermentation process, but it suffers from low efficiency, high costs, and enzyme instability, as well as high energy consumption.^{5,6} Given the aforementioned challenges in amino acid synthesis, it is highly desirable to develop efficient and green methods for the production of amino acids from renewable feedstocks.

Biomass is a renewable organic carbon resource, and is a potential alternative to the dwindling fossil fuel reserves. Lignocellulose is the most abundant biomass on Earth, which can be easily converted into various oxygen-containing platform molecules, such as lactic acid and furfural.^{7–15} Chitin is the second most abundant biopolymer with an annual production of 100 Gt, consisting of *N*-acetylglucosamine (NAG) and glucosamine units linked by β -1,4-glycosidic bonds.¹⁶ In the past few decades, great advances have been achieved in the catalytic conversion of biomass to valued chemicals and liquid fuels.^{6,17–25} However, the “functional group gap” between amino acids and biomass constituents has made the production of amino acids from biomass notoriously difficult, as amino acids simultaneously contain amine groups and carboxyl groups, which are absent in biomass constituents.

In 2018, Yan's group pioneered a novel chemocatalytic method for synthesizing α -amino acids through the amination of lignocellulose-derived α -hydroxyl acids using NH_3 over Ru-based heterogeneous catalysts.¹¹ A series of α -amino acids, including alanine, leucine, valine, aspartic acid, and phenylalanine, were efficiently obtained.^{11–13} Apart from α -hydroxyl

acids, glycerol and furfural were also reported recently as starting substrates for preparing alanine and proline, respectively.¹⁴ Meanwhile, the production of amino acids, such as glucosaminic acid and tyrosine, from the natural nitrogen-containing polymer chitin has also been demonstrated through the chemocatalytic method.^{15,26}

The chemocatalytic method with biomass as a renewable feedstock has great potential to improve the synthesis efficiency and reduce carbon footprint in amino acid synthesis.^{27–30} Currently, the number of review articles on renewable production of nitrogen-containing chemicals from biomass is vast. However, the literature lacks an overview on the production of amino acids from biomass. While this method is still in its infancy, it is highly desirable to give a comprehensive overview of amino acid synthesis, which is the subject of this perspective article. This perspective starts with a brief introduction on existing methods for amino acid synthesis. Then, we mainly focus on two categories for the production of amino acids from biomass through the chemocatalytic method (Fig. 1). The first is to catalytically convert biomass-derived oxygen-containing feedstocks to amino acids by introducing N-functional groups. The second section involves utilizing chitin-derived nitrogen-containing feedstocks as starting materials for the catalytic synthesis of amino acids. In the end, a number of challenges and opportunities are highlighted for the chemocatalytic amino acid synthesis from biomass.

2 Existing methods for amino acid synthesis

2.1 Chemical synthesis

The Strecker synthesis is the oldest known chemical synthesis of α -amino acids, as reported by Adolph Strecker in 1850 (Fig. 2).³² It begins with the condensation of NH_3 to an aldehyde, forming an imine. Afterwards, the addition of a cyanide ion to an imine produces an α -aminonitrile. This is then hydrolyzed to yield racemic α -amino acid under acidic conditions. By varying the R group on the aldehyde, a series of α -amino acids are synthesized through the Strecker synthesis.^{33,34} To address the issue of chirality, the asymmetric Strecker synthesis has been developed.^{35–39} For example, Zuend *et al.*³ utilized a chiral amino-thiourea catalyst that was compatible with aqueous cyanide salts to achieve the asymmetric Strecker synthesis of unnatural α -amino acids. Although the Strecker synthesis has been well studied, the utilization of highly toxic cyanide sources inevitably limits its practical application.³ So far, only a limited number of amino acids have been commercially produced through this method. For example, methionine, used as feed additives in industrial livestock farming, can be produced by the Strecker synthesis using methyl mercaptan, acrolein and hydrogen cyanide. The entire process has been ongoing at Evonik Degussa in Germany for 50 years and contributed to 60% of the world's methionine capacity in 2014.⁴⁰

Xingang Li

Xingang Li is the Dean of the Department of Catalysis Science & Engineering and Chair Professor at Tianjin University. He received his BS (1998) and Ph.D. degrees (2003) from the University of Science & Technology of China. After finishing postdoctoral research at IRCELYon (France) and the University of Patras (Greece), in 2007 he joined the School of Chemical Engineering & Technology of Tianjin University.

His research interests include energy catalysis and environmental catalysis. He has published more than 160 articles, served as the Associate Editor of “Journal of Chemical Technology & Biotechnology”, and was awarded the “Young Scientist Award” by the International Association of Catalysis Societies.

Fig. 1 Production of amino acids from biomass through the chemocatalytic method.

Fig. 2 The Strecker synthesis of α -amino acids.^{3,31}

Fig. 3 The fermentation process for amino acid synthesis.

2.2 Biological synthesis

Biological synthesis can be divided into two categories: enzymatic synthesis and fermentation process. Enzymatic synthesis means the utilization of enzymes to facilitate the production of specific amino acids from proteins. For example, the efficient production of alanine, leucine, and glutamic acid from dried fish protein has been achieved with the combination of alcalase and neutrase enzymes.⁴¹ One notable advantage of enzymatic synthesis is the production of optically pure D- or L-amino acids at high substrate concentrations while minimizing the by-product formation.⁵ Nonetheless, enzymes are costly and lack stability, rendering them unsuitable for the large-scale industrial production of amino acids. To date, the commercial applications of enzymatic synthesis for the production of amino acids, such as L-aspartic acid and L-alanine, have had only limited success.⁴²

Currently, the industrial production of amino acids mainly depends on the fermentation process (Fig. 3). *Corynebacterium glutamicum* (*C. glutamicum*) and *Escherichia coli* (*E. coli*) are two of the most commonly used bacteria in this process.⁴³ These two bacteria have the ability to generate a wide range of amino acids, and various metabolic engineering modifications have also been implemented to enhance their efficiency in amino acid synthesis. For example, the genetically modified

C. glutamicum was successfully employed for high-yield production of L-lysine and L-glutamic acid.^{44,45} The modified *E. coli* has been developed to facilitate the production of valuable aromatic amino acids such as L-tryptophan, L-phenylalanine, and L-tyrosine.⁴⁶ Notably, the fermentation process exclusively produces L-form amino acids, thus obviating additional purification steps. Furthermore, it can be operated under mild conditions to prevent product degradation. However, the fermentation process necessitates sterile conditions, and suffers from high energy consumption, low production efficiency, as well as high capital and operational costs.⁴⁷

3 Amino acid synthesis through the chemocatalytic method

3.1 Lignocellulose

3.1.1 α -Hydroxyl acids. α -Hydroxyl acids, containing hydroxyl and carboxyl groups, are readily available from various lignocellulose constituents. For example, lactic acid was quantitatively obtained from glucose in the presence of Ba(OH)₂ at room temperature.¹¹ Heteropolyacid catalysts could

Fig. 4 Thermocatalytic, photocatalytic, and electrocatalytic conversion of α -hydroxyl acids into α -amino acids.

afford 49% glycolic acid directly from cellulose through selective oxidation.⁴⁸ In principle, it seems to be a promising strategy for the production of α -amino acids from α -hydroxyl acids, in which the key chemistry is to construct an amine group $-NH_2$ via amination with the carboxyl group $-COOH$ remaining intact. In the following section, we will introduce the recent progress in the thermocatalytic, photocatalytic, and electrocatalytic conversion of α -hydroxyl acids to α -amino acids (Fig. 4).

Thermocatalytic system. In 2018, Deng *et al.* first reported the production of α -amino acids from α -hydroxyl acids and NH_3

over a thermocatalytic system.¹¹ Using 3 wt% Ru/CNT catalyst in NH_3 aqueous solution at 220 °C and 10 bar H_2 , alanine was efficiently obtained *via* the amination of lactic acid with the maximum yield of 62% (Fig. 5). Moreover, a two-step strategy was developed for the conversion of glucose to alanine in 43% yield. Afterwards, extensive research efforts were devoted to develop highly efficient thermocatalytic systems for amino acid synthesis from α -hydroxyl acids.^{49–52} For example, Xie *et al.* reported that N-doped carbon nanotube-supported Ru nanoparticles (Ru/N-CNTs) exhibited a remarkable performance in the amination of lactic acid, in which the maximum alanine yield of 70% was obtained at 180 °C and 10 bar H_2 for 2 h.⁵² The outstanding activity of the Ru/N-CNT catalyst was mainly attributed to the highly dispersed Ru nanoparticles, the strong electronic interaction between Ru nanoparticles and N-CNTs, and the enhanced adsorption of lactic acid through basic sites. Xin *et al.* prepared a magnetic catalyst Ru/Ni@C by ethylene glycol reduction of metal Ru supported on encapsulated Ni@C.⁵¹ The best catalytic performance was obtained with a lactic acid conversion of 70% and an alanine yield of 64% at 200 °C and 15 bar H_2 for 2 h. The formed RuO_2 species, acting as Lewis acid sites, could improve the activation of the hydroxyl group of lactic acid as well as the adsorption ability of NH_3 , accordingly facilitating the amination of lactic acid to alanine. In addition, Wang *et al.* reported a one-step protocol to convert glycerol into alanine with lactic acid as an intermediate over a Ru_1Ni_7/MgO catalyst in the presence of NaOH.¹⁴ Alanine with a yield of 43% was obtained, which is comparable with the yield of alanine (41%) produced from microbial cultivation processes.⁵³ The formation of Ru–Ni alloys in the Ru_1Ni_7/MgO catalyst promoted C–H activation in the conversion of glycerol to lactic acid and the amination of lactic acid.

Fig. 5 Thermocatalytic conversion of lactic acid and NH_3 into alanine using a Ru-based catalyst.^{11,49,52}

A series of α -amino acids, including alanine, α -aminobutyric acid, valine, leucine, aspartic acid, and phenylalanine, have been successfully obtained through the thermocatalytic amination of α -hydroxyl acids. However, high reaction temperature ($>180\text{ }^{\circ}\text{C}$) is necessary to overcome the energy barrier for the dehydrogenation of hydroxyl groups of α -hydroxyl acids, which will in turn induce the formation of side products, such as ethanol, propionic acid, and propenamide.^{11,49} Therefore, developing high-efficient and selective catalysts for amino acid synthesis at low temperatures is highly desirable for future research.

Photocatalytic system. In the 1990s, attempts were made to synthesize amino acids under light irradiation. However, only commercially available semiconductors in the bulk form were investigated and their photocatalytic activities were extremely low without synthetic interest.^{54,55} In 2020, Song *et al.* prepared a series of CdS semiconductors with different morphologies and successfully applied them to the photocatalytic amino acid synthesis from α -hydroxyl acids under visible light irradiation.¹³ The highest alanine productivity ($10.5\text{ mmol h}^{-1}\text{ g}_{\text{cat}}^{-1}$) was obtained over ultrathin CdS nanosheets at $50\text{ }^{\circ}\text{C}$ and 1 bar N_2 , higher than that obtained in the thermocatalytic system ($3.1\text{ mmol h}^{-1}\text{ g}_{\text{cat}}^{-1}$, 3 wt% Ru/CNT). The reaction mechanism for the photocatalytic conversion of lactic acid to alanine is shown in Fig. 6. First, the dehydrogenation of lactic acid to pyruvic acid was triggered by photogenerated holes. Then, the self-addition of pyruvic acid with NH_3 to imino acid occurred. Finally, photogenerated electrons reduced imino acid to alanine.^{13,56} In addition, the production of H_2 was regarded as a major side reaction, which would consume photogenerated electrons. Also, alanine could be further converted into alaninamide upon increasing the reaction time, resulting in low selectivity.¹³ Afterwards, Fu *et al.*⁵⁶ prepared a highly fused CdS/ Ti_3C_2 MXene Schottky junction photocatalyst, which significantly enhanced the alanine productivity ($33.7\text{ mmol g}^{-1}\text{ h}^{-1}$). The formation of the CdS/ Ti_3C_2 Schottky junction not only enhanced the separation efficiency of photo-

generated charges, but also inhibited the recombination of photoexcited electrons–holes, accordingly facilitating the photocatalytic activity.

Unlike the thermocatalytic process, photocatalysis could utilize photogenerated charge carriers to activate substrates, easily generating active radical species as key intermediates, which enables the conversion of α -hydroxyl acids to be efficiently conducted under mild conditions. Thus, amino acid synthesis through the photocatalytic system is a very green method. However, the overall yields of amino acids currently are limited ($<30\%$) in the photocatalytic system, possibly resulting from the further photocatalytic conversion of alanine to by-products, such as alaninamide and pyruvic acid.^{12,13} It is highly desirable to develop highly efficient photocatalytic systems to inhibit undesired side reactions, such as H_2 production.

Electrocatalytic system. In 2022, Sun *et al.* reported an electrochemical strategy for synthesizing α -amino acids with high yields from α -hydroxyl acids and NH_2OH or NH_3 .¹² The electrocatalytic system mainly consists of two steps: (1) selective oxidation of α -hydroxyl acids to α -keto acids at the anode; (2) reduction of oxime (or imine) intermediates obtained from α -keto acids at the cathode. Also, a flow cell was successfully developed for the continuous conversion of α -hydroxyl acids to α -amino acids. More recently, wasted nitrogen resources (NO and NO_3^-) are adopted in the electrocatalytic system for synthesizing α -amino acids from α -keto acids, which are key intermediates in the amination of α -hydroxyl acids to α -amino acids. For example, Zhang *et al.*⁵⁷ reported an electrocatalytic system for synthesizing alanine from NO and pyruvic acid. They designed a spatially decoupled two-pot electrocatalytic system that utilized flow reactors loaded with oxide-derived Ag for the production of alanine. 3.85 g of alanine with a total faradaic efficiency of 70% and a purity of $>98\%$ was obtained at a current density of 100 mA cm^{-2} . Wang *et al.*⁵⁸ reported the electrosynthesis of alanine with a maximum yield of 55% from pyruvic acid and NO_3^- catalyzed by PdCu nanobead wire (Fig. 7). The conversion of pyruvic acid and NO_3^- to alanine is

Fig. 6 Photocatalytic conversion of lactic acid and NH_3 into alanine.¹³

Fig. 7 Electrocatalytic conversion of pyruvic acid and nitrate into alanine. Adapted and modified with permission from ref. 58. Copyright 2023 John Wiley and Sons.

a tandem process: NO_3^- was first electroreduced to the $^*\text{NH}_2\text{OH}$ intermediate, which could interact with pyruvic acid to form pyruvic oxime, and then the pyruvic oxime was electroreduced to yield alanine.

The electrocatalytic system can separate the production of α -amino acids into two half-reactions: dehydrogenation and reductive amination, which are conducted at the anode and cathode, respectively. The main advantage of the electrocatalytic system is to prevent the further conversion of α -amino acids, which is inevitable in the reported thermocatalytic and photocatalytic systems.^{59–62} However, complex electrolytes, organic solvents, and a large number of organic bases are normally used in the electrocatalytic system. Also, the utilization of expensive α -keto acids as substrates is not cost-effective.

Finally, we have summarized the merits and limitations of the thermocatalytic, photocatalytic, and electrocatalytic conversion of α -hydroxyl acids to α -amino acids in Table 1.

3.1.2 Furfural. Furfural is a low-cost (1.0–1.2 € per kg) and widely available lignocellulose-derived platform molecule with an annual production of over 600 kT.⁶³ It serves as a suitable substrate for the production of cyclic amino acids. In 2020, Song *et al.* reported the production of D-proline from furfural through a procedure combining chemical and biological processes (Fig. 8).⁶⁴ First, a dual-layer catalytic system (Pd@S-1 + H-Beta) was designed to achieve one-step conversion of furfural to pyrrole *via* a tandem decarbonylation–amination reaction, obtaining an overall yield of 75% under optimal conditions. Pyrrole was then converted to DL-proline through a two-step process, involving carboxylation with CO_2 and subsequent hydrogenation. After treating with *E. coli*, D-proline was obtained in a theoretically maximum yield of 50% with excellent ee (>99%).

3.2 Chitin and its derivatives

Chitin contains naturally fixed nitrogen in the form of amide functionality, which renders it as an ideal resource for produ-

cing various N-containing chemicals without the addition of nitrogen sources.⁶⁵ Since the concept of “shell biorefinery” was proposed by Yan *et al.* in 2015, various N-containing chemicals, such as amino acids, have been efficiently produced from chitin and its derivatives.^{16,66–73}

As the monomer of chitin, NAG serves as an ideal substrate for the production of amino acids. For example, Ebitani *et al.* successfully achieved the aerobic oxidation of NAG to the corresponding amino acid over supported Au catalysts in water under mild conditions.⁷⁴ Fukuoka *et al.*⁷⁵ reported a two-step chemocatalytic method for the production of a commonly used amino acid in a protected form, acetylglycine, from NAG. In the first step, the catalytic conversion of NAG to *N*-acetyl monoethanolamine was achieved over Ru/C catalysts in NaHCO_3 aqueous solution under H_2 pressure.^{76,77} In the second step, the same combination of Ru/C- and NaHCO_3 -catalyzed oxidation of *N*-acetyl monoethanolamine to acetylglycine was achieved under an O_2 atmosphere. The Ru species in Ru/C were present as small hydrous RuO_2 clusters, which were identified as catalytically active sites for the oxidation of *N*-acetyl monoethanolamine. In addition, Dai *et al.* reported the tandem production of glucosaminic acid from chitosan, a partially deacetylated chitin (Fig. 9).¹⁵

Chitin is also directly utilized for the production of amino acids. Yan and Zhou *et al.* reported the production of two aromatic amino acids (tyrosine and levodopa (L-DOPA)) directly from shell waste-derived chitin *via* an integrated biorefinery process, which involved a chemical pretreatment of chitin-containing shell waste and an enzymatic/fermentative bioprocess using metabolically engineered *E. coli* (Fig. 10).²⁶ The engineered *E. coli* strains produced 0.91 g L^{-1} tyrosine or 0.41 g L^{-1} L-DOPA from 22.5 g L^{-1} unpurified shell waste-derived chitin hydrolysates.

Table 1 The merits and limitations of the thermocatalytic, photocatalytic, and electrocatalytic conversions of α -hydroxyl acids into α -amino acids

Catalytic systems	Merits	Limitations
Thermocatalysis	High efficiency Large scale	Harsh conditions Noble metal catalysts
Photocatalysis	Mild conditions Semiconductors	Limited yields Poor stability
Electrocatalysis	Mild conditions Continuous production	Complex electrolytes Noble metal catalysts

4 Conclusions and outlook

Highly efficient and green production of amino acids is of great significance in pursuit of a sustainable future. The chemocatalytic method has emerged as a promising strategy for the renewable production of amino acids from biomass, which has great potential to improve the amino acid synthesis efficiency and reduce carbon footprint. In this perspective, we introduce the significant advances that have been made in the chemocatalytic amino acid synthesis from various biomass constituents, including α -hydroxyl acids, furfural, glycerol, and chitin and its derivatives. With the remarkable progress, the chemocatalytic method will play a more important role in the field of amino acid synthesis in the future. We believe that this perspective can inspire many future studies using this method. Hence, we hope to share our perspective on the opportunities and challenges in amino acid synthesis through the chemocatalytic method.

4.1 New reaction routes

There exist many opportunities for discovering new reaction routes for producing amino acids from biomass. For example, glycine is the simplest amino acid composed of only two carbons and one amino group, which can be obtained from the oxidation of ethanolamine. Since the production of ethanolamine from cellulose has been reported,⁷⁸ it has great potential to directly produce glycine from cellulose. Hemicellulose, mainly composed of 5-carbon sugars, serves as a suitable substrate for the production of 5-carbon amino acids, such as glutamic acid. Lignin, as one of the main components of lignocellulose, is the most abundant renewable aromatic source on Earth and is an ideal resource for the production of aromatic amino acids. For example, tyrosine may be synthesized from lignin with *p*-coumaric acid as a key building block.

Several amino acids have been successfully obtained from biomass *via* multi-step reactions. For example, glucosaminic acid has been obtained from chitosan *via* consecutive hydrolysis, deacetylation, and oxidation.¹⁵ Also, the production of proline from furfural *via* decarbonylation, amination, carboxylation, and hydrogenation has been demonstrated.⁶⁴ However, the complex reaction procedure would inevitably induce high energy consumption, excessive carbon emissions, and expensive investment. Thus, designing novel chemocatalytic systems that enable combining the existing multiple reaction steps into a single reactor is highly desirable.

4.2 Chirality

Chirality is crucial for amino acids, especially for their application in the pharmaceutical field. However, it is still challenging to synthesize chiral amino acids through the chemocatalytic method. Developing hybrid catalytic systems seems to be a promising strategy for synthesizing chiral amino acids through the chemocatalytic method. For example, the photo-thermal catalytic system consisting of semiconductors as light harvesters grafted with homogeneous asymmetric catalysts has

great potential to achieve the production of chiral amino acids from biomass.

The chiral resolution has been demonstrated as an effective method for separating two racemic amino acids, which includes kinetic resolution, chromatographic resolution, crystallization resolution, and membrane-based resolution.^{4,79} Thus, integrating this process with the chemocatalytic method can also achieve the conversion of biomass into chiral amino acids, but they have been rarely reported so far.

4.3 New catalytic systems

The key to the chemocatalytic method is the rational design and preparation of novel catalysts. Take the example of α -amino acids discussed in Fig. 4. Ru-based catalysts have been demonstrated to be effective for the thermocatalytic amination of α -hydroxyl acids to α -amino acids. Currently, the majority of existing research mainly focuses on the development of robust Ru-based catalysts *via* the trial-and-error method. Limited attention has been paid to explore the active sites and the related reaction mechanisms. *In situ* characterization studies are highly recommended to observe structural changes of catalysts under reaction conditions and provide insights into surface-adsorbed species and reaction intermediates.

CdS-based photocatalysts exhibit unique catalytic performance in the photocatalytic amination of α -hydroxyl acids to α -amino acids. However, they suffer from photocorrosion under light irradiation. Suitable strategies for improving their resistance to photocorrosion are highly desirable. Additionally, the practical application of the CdS-based photocatalytic system is impeded by the intrinsic toxicity of cadmium ions. Future research should focus on developing more robust and eco-friendly materials. For example, transition-metal (oxy) nitride photocatalysts, such as TiO_xN_y , which are promising materials for a wide range of redox reactions such as overall water splitting,⁸⁰ may hold great potential for amino acid synthesis.
