# Flexible direct synthesis of phosphorus-rich $\text{CoP}_3$ on carbon black and its examination in hydrogen evolution electrocatalysis†

Ishanka A. Liyanage,<sup>1</sup> Hannah Barmore and Edward G. Gillan<sup>1</sup>\*

In contrast to metal-rich cobalt phosphides, phosphorus-rich  $\text{CoP}_3$  is less studied as a hydrogen evolution reaction (HER) electrocatalyst, though it has distinct polyphosphide structural features and electronic properties that can be useful in facilitating proton reduction. While bulk crystalline solids are ideal surfaces for electrocatalytic studies, methods to disperse active catalysts on inexpensive high surface area supports can lead to improved HER activity with less catalyst. This paper describes a straightforward two-step procedure to produce a series of crystalline  $\text{CoP}_3$  particles supported on conducting carbon black powder. Anhydrous  $\text{CoCl}_2$  was deposited onto carbon black in various amounts from a methanol solution. The dried  $\text{CoCl}_2/\text{C}$  products were directly reacted with elemental phosphorus in an ampoule at 500 °C. These reactions produce crystalline  $\text{CoP}_3/\text{C}$  with nominally 5–25 mol% of  $\text{CoP}_3$  on carbon black. These  $\text{CoP}_3/\text{C}$  composites possess a  $\sim 3$  to 10 times higher surface area ( $\sim 11$ – $35 \text{ m}^2 \text{ g}^{-1}$ ) versus similarly synthesized bulk  $\text{CoP}_3$ . The  $\text{CoP}_3$  crystallites grow in aggregated form with carbon black nanoparticles. The HER electrocatalytic behavior of these composites in 0.5 M  $\text{H}_2\text{SO}_4$  was evaluated and all  $\text{CoP}_3/\text{C}$  composites were HER active and require only applied potentials near  $-95 \text{ mV}$  to achieve  $10 \text{ mA cm}^{-2}$  current densities. The lower content  $\text{CoP}_3$  catalyst particles dispersed on carbon black show similar HER activity to bulk  $\text{CoP}_3$ . These  $\text{CoP}_3/\text{C}$  composites are stable in acid and show a high degree of electrocatalytic stability in extended time HER electrocatalytic experiments.

## Introduction

Sustainable, cost-effective, and efficient processes for energy conversion and storage remain a crucial environmental and economic challenge. Molecular hydrogen as an excellent energy carrier and can be produced without carbon emissions, and so it is a key component in meeting future energy demands.<sup>1–4</sup> The hydrogen evolution reaction (HER) can be catalytically driven using electrochemical or photochemical means *via* water splitting ( $2\text{H}_2\text{O} \rightarrow 2\text{H}_2 + \text{O}_2$ ) and is important for renewable and green energy strategies in a hydrogen economy.<sup>5–8</sup> Precious metal-based catalysts such as platinum are very efficient HER electrocatalysts, but low abundance and high cost have impeded their practical wide scale use. Extensive efforts are underway to identify effective, efficient, and less expensive HER electrocatalysts using earth-abundant elements in compounds including

metal borides, carbides, nitrides, oxides, sulfides, selenides, and phosphides.<sup>9–13</sup> Among these materials, metal phosphides are a diverse class of compounds including metal rich ( $\text{M}_x\text{P}_y$ ;  $x > y$ ) and phosphorus rich ( $\text{M}_x\text{P}_y$ ;  $x < y$ ) structures that exhibit electrocatalytic HER activity. Nanostructured, metal-rich and monophosphides have also shown impressive HER catalytic performance.<sup>14–17</sup> The metal-rich phosphides have exposed metal surface sites along with nearby phosphorus for proton binding, reduction, and moderate stability during acidic HER electrocatalysis. In contrast, phosphorus-rich structures have metal and polyphosphide anion bonding arrangements that can modify proton–surface interactions, reduction processes and may improve corrosion resistance during acidic HER electrocatalysis.<sup>18,19</sup>

In energy applications, cobalt phosphides are widely studied as active materials in fuel cell, battery, and HER electrocatalytic applications. The phosphorus-rich  $\text{CoP}_3$  has been examined as a thermoelectric and lithium or sodium-ion battery material.<sup>20–22</sup> A variety of nanostructured, free-standing, metal-rich phosphides and monophosphides including  $\text{Co}_2\text{P}$ , and  $\text{CoP}$  with different morphologies show promising HER performance in acidic conditions. Several cobalt phosphides supported on titanium foil ( $\text{Co}_2\text{P}$  nanorods, hollow  $\text{Co}_2\text{P}$  nanoparticles, uniform, multifaceted  $\text{CoP}$

nanoparticles) and CoP nanowires on a glassy carbon electrode (GCE) produce  $10 \text{ mA cm}^{-2}$  current density at very low applied potentials of  $-75 \text{ mV}$  to  $-134 \text{ mV}$ .<sup>14</sup> The HER applied potentials markedly decrease with the increase of phosphorus content in Co-P phases (CoP *versus*  $\text{Co}_2\text{P}$ ), indicating that more phosphorus-rich structures can exhibit higher HER activities and stabilities.<sup>23</sup>

Several recent theoretical studies describe value in phosphorus-rich surface structures that can favor hydrogen adsorption and reduction in HER catalysis.<sup>18,24,25</sup> The phosphorus rich Co-P phases, including  $\text{CoP}_2$  and  $\text{CoP}_3$  are much less studied as electrocatalysts. Bulk  $\text{CoP}_2$  nanoparticles require applied negative potentials of  $-120 \text{ mV}$  to achieve  $10 \text{ mA cm}^{-2}$  in  $0.5 \text{ M H}_2\text{SO}_4$ .<sup>26</sup> The most phosphorus-rich phase,  $\text{CoP}_3$ , has a cubic, skutterudite ( $\text{CoAs}_3$ ) crystal structure with  $\text{P}_4^{4-}$  polyanion rings,  $\text{Co}^{3+}$  cations, has a small semiconductor band gap ( $E_g \sim 0.45 \text{ eV}$ ), and is typically produced in high temperature elemental ( $\sim 1000 \text{ }^\circ\text{C}$ ) solid-state reactions.<sup>27-30</sup> Crystalline  $\text{CoP}_3$  nanowires and  $\text{CoP}_3$  nanoparticles require applied potentials of  $-247 \text{ mV}$  and  $-122 \text{ mV}$ , respectively to achieve a  $10 \text{ mA cm}^{-2}$  current density.<sup>31,32</sup> We recently reported a straightforward solvent-free moderate temperature ( $500 \text{ }^\circ\text{C}$ ) route to crystalline  $\text{CoP}_3$  and other phosphorus-rich  $\text{MP}_2/\text{MP}_3$  structures ( $\text{M} = \text{Fe}, \text{Ni}, \text{Cu}$ ) and demonstrated that crystalline  $\text{CoP}_3$  microparticles are very effective in HER electrocatalysis in  $0.5 \text{ M H}_2\text{SO}_4$  at low applied negative potentials of  $-147 \text{ mV}$  to achieve a  $10 \text{ mA cm}^{-2}$  current density.<sup>33</sup> This solvent-free method has been extended to a range of metal-rich to phosphorus-rich nickel phosphides that show HER activity.<sup>34</sup>

One potentially useful way to maintain or enhance electrocatalytic performance with lower catalyst amounts is to deposit/composite active catalysts on/with electrically conductive carbon-based supports.<sup>35-39</sup> Catalyst-support interactions are reported to impact interfacial charge transfer that can result in more effective electrocatalytic activity.<sup>40-42</sup> Carbon black (*e.g.*, Vulcan XC-72) is a commonly employed high surface areas support in electrochemical studies and is used to disperse and stabilize platinum nanoparticles, to prevent agglomeration, and to reduce metal usage.<sup>38,39</sup> Carbon-supported materials such as metal nitrides, sulfides, selenides, and phosphides have been studied in battery electrochemistry and in electrocatalytic reactions such as the hydrogen evolution reaction (HER), oxygen evolution reaction (OER), and oxygen reduction reaction (ORR).<sup>9,35,43,44</sup> Recent catalyst materials intimately embedded in conducting carbons have been produced from pyrolysis of metal-organic frameworks.<sup>45</sup>

Carbon-supported metal-rich and monophosphides of several earth-abundant 3d transition metals (Fe, Co, Ni, Cu) have shown improved HER activity relative to their free-standing counterparts. Typical syntheses of carbon-supported cobalt phosphides require multiple synthetic steps such as hydro/solvothermal reactions of metal salt precursors, followed by moderate temperature ( $\sim 350\text{--}500 \text{ }^\circ\text{C}$ ) phosphidization using toxic  $\text{PH}_3$  gas.<sup>23,46-48</sup> These syntheses usually produce disordered or amorphous metal-rich  $\text{Co}_2\text{P}$  and CoP nanomaterials and high temperature annealing is required to obtain crystalline products.  $\text{Co}_2\text{P}$  and CoP materials supported on high surface area carbon nanotubes (CNTs) exhibit improved HER activity, achieving  $10 \text{ mA cm}^{-2}$  current density at applied potentials of  $-195 \text{ mV}$

and  $-165 \text{ mV}$  respectively, which are about  $200 \text{ mV}$  lower than measured for the bulk phosphide catalysts.<sup>46-50</sup> CoP supported on nitrogen-doped CNTs shows high HER activity with an applied potential of only  $-99 \text{ mV}$  to achieve a  $20 \text{ mA cm}^{-2}$  current density.<sup>23</sup> Rare examples of supported phosphorus-rich cobalt phosphides on carbon supports include  $\text{CoP}_2$  on reduced graphene oxide (RGO) that shows HER activity at  $\sim 30 \text{ mV}$  lower applied potentials than required for free-standing  $\text{CoP}_2$  nanoparticles.<sup>26</sup> Crystalline  $\text{CoP}_3$  nanoarrays grown on carbon fiber paper are efficient HER electrocatalysts at low applied potentials of  $-65 \text{ mV}$  to attain a  $10 \text{ mA cm}^{-2}$  current density.<sup>40</sup>  $\text{CoP}_3$  nanoparticles combined with carbon black *via* ball milling produce poorly crystalline nanocomposite mixtures of carbon-coated  $\text{CoP}_3$  with CoP and cobalt carbide phases ( $\text{Co}_2\text{C}$  and  $\text{CoC}_x$ ) that were investigated as anode electrode materials for sodium-ion batteries.<sup>20</sup>

Our prior work on the solvent-free synthesis and properties of bulk crystalline microparticulate  $\text{MP}_2/\text{MP}_3$  demonstrated that crystalline  $\text{CoP}_3$  is very effective for electrocatalytic HER.<sup>33</sup> In this study, we demonstrate that a tunable modification of our direct  $\text{CoP}_3$  synthesis method is successful for the growth of varying amounts of crystalline  $\text{CoP}_3$  distributed on a conducting carbon black powder support. Changes in electrocatalytic HER activity were investigated *versus* catalyst composition for these  $\text{CoP}_3/\text{C}$  composite structures. The influence of  $\text{CoP}_3$  catalyst content and physical or electrochemically active surface area on HER activity is described.

## Experimental procedures

### Starting materials

The cobalt phosphide materials were synthesized using sealed Pyrex ampoules (I.D.  $\sim 9 \text{ mm}$ , O.D.  $\sim 13 \text{ mm}$ ). The reagents used as received were:  $\text{CoCl}_2$  (anhydrous, Alfa Aesar, 99.8%), red phosphorus (Aldrich, vacuum dried  $60 \text{ }^\circ\text{C}$ , 99%), Vulcan XC-72 carbon black (Cabot),  $12 \text{ M HCl}$  (Fisher Scientific), and methanol (Fisher Scientific, 99.9%). Deionized water ( $18 \text{ M}\Omega$ ) was obtained from a Photronix MiniQuad system. For electrochemical studies, the following materials were used: synthetic graphite powder ( $< 20 \text{ }\mu\text{m}$ , Sigma-Aldrich), paraffin wax ( $\text{mp} \geq 65 \text{ }^\circ\text{C}$ , Sigma-Aldrich), concentrated  $\text{H}_2\text{SO}_4$  (Certified ACS Plus 95–98%, Fisher Scientific), and 10% Pt on Vulcan XC-72 carbon (C1-10 fuel cell grade, E-Tek).

### Reaction safety considerations

All reactions described here were carried out in evacuated sealed Pyrex glass ampoules and utilizes red phosphorus that converts to pyrophoric molecular white phosphorous/ $\text{P}_4$  vapor above  $\sim 400 \text{ }^\circ\text{C}$ . The maximum pressure ( $< 7 \text{ atm}$ ) built inside the ampoule must be estimated from ideal gas law prior to each experiment to avoid any ampoule explosions. Ampoules must be heated in a well-ventilated fume hood to avoid any damage from an accidental explosion. Careful attention should be paid to opening the ampoule in a fume hood since transport end may present unreacted pyrophoric  $\text{P}_4$  and/or  $\text{PCl}_3$  liquid

byproduct which fumes in contact with air. The transport should be carefully decomposed by oxidation using aqueous bleach solutions and the product should be well air ventilated in the fume hood prior isolation. The hazardous use of concentrated acids (HCl and H<sub>2</sub>SO<sub>4</sub>) in product isolation, chemical analysis, and electrochemistry must be carefully performed in a fume hood with proper protective gear. Careful attention to personal safety must be also performed for carbon-wax electrode preparation that utilizes razor blades and hot wax injection into Teflon tubing.

#### Deposition of $x$ -CoCl<sub>2</sub> ( $x = 5, 10, 25$ mol%) on carbon black

Different amounts of anhydrous cobalt chloride,  $x$ -CoCl<sub>2</sub> ( $x = 5, 10, 25$  mol% vs. C), were deposited on carbon black using methanol evaporation and drying of cobalt chloride and carbon black precursors to produce  $x$ -CoCl<sub>2</sub>/C composites. Typically, 0.650 g (5.0 mmol), 0.262 g (2.0 mmol) and 0.132 g (1.0 mmol) of CoCl<sub>2</sub> were deposited on 0.182 g (15.1 mmol), 0.219 g (18.2 mmol), 0.229 g (19.0 mmol) of carbon black respectively to obtain 25-CoCl<sub>2</sub>/C, 10-CoCl<sub>2</sub>/C and 5-CoCl<sub>2</sub>/C precursor materials, respectively. The precursor materials were added to a 250 mL Schlenk flask with a stir bar in an argon filled glove box, the flask was covered with a rubber septum, the flask stopcock was closed and removed from the glove box. The flask was purged with nitrogen on a Schlenk line and approximately 30 mL of degassed methanol was cannula transferred onto the precursor mixture. The suspended dark solution was further degassed while stirring for several minutes and the rubber septum of the flask was replaced with a glass stopper. The flask was placed in a water bath (~50 °C), was evacuated and the methanol was removed and condensed in a liquid nitrogen cold trap. The dry powder was then heated under vacuum at 180 °C for ~15 minutes in a heating mantle. The closed flask was removed from the Schlenk line, returned to glove box, and weighed.

#### Synthesis of CoP<sub>3</sub> and $x$ -CoP<sub>3</sub>/carbon black ( $x = 5, 10, 25$ mol%) composites

Based on our prior reports of phosphorus-rich metal phosphide growth, CoP<sub>3</sub>/C composites were synthesized in sealed ampoule from direct stoichiometric reaction of anhydrous  $x$ -CoCl<sub>2</sub>/C and red phosphorus at 500 °C to produce CoP<sub>3</sub> and PCl<sub>3</sub> (mp/bp = -94/76 °C). For comparison, bulk CoP<sub>3</sub> was synthesized using 0.133 g (1.0 mmol) of CoCl<sub>2</sub> and 0.115 g (3.7 mmol) of red phosphorus. The  $x$ -CoP<sub>3</sub>/carbon black composites were synthesized from direct reactions of  $x$ -CoCl<sub>2</sub>/C precursors ( $x = 5, 10, 25$  mol% vs. C) with excess red phosphorus (~3–5 times more than stoichiometric) in sealed ampoules. Typical reagent amounts used are 25-CoP<sub>3</sub>/C reaction with 0.132 g (0.8 mmol) of 25-CoCl<sub>2</sub>/C and 0.269 g (8.6 mmol) of red phosphorus, 10-CoP<sub>3</sub>/C reaction with 0.131 g (0.55 mmol) of 10-CoCl<sub>2</sub>/C and 0.185 g (6.0 mmol) of red phosphorus, and 5-CoP<sub>3</sub>/C reaction with 0.098 g (0.28 mmol) of 5-CoCl<sub>2</sub>/C and 0.162 g (5.2 mmol) of red phosphorus.

The starting materials were ground together in an argon filled glove box with an agate mortar and pestle and loaded into

Pyrex glass ampoule, which was then closed with a Cajon fitting and Teflon valve and removed from the glove box. Each tube was evacuated on a Schlenk line for ~15 minutes, and then the tube was flame sealed. The evacuated, sealed ampoule was heated in a horizontal tube furnace (Lindberg Blue M-clamshell) to 500 °C at a heating rate of 100 °C h<sup>-1</sup> and reaction was held at 500 °C for ~48 hours.

After the reaction, the end of the tube without solid was pulled out of the furnace and cooled to near room temperature and a colorless PCl<sub>3</sub> liquid condensed on the cooled glass walls. When no further liquid condensed, the entire tube was cooled to room temperature. The cooled tube was cracked open in air in the fume hood, carefully keeping the fuming liquid PCl<sub>3</sub> away from the solid. The solid was allowed to sit in air for several minutes and then washed with methanol for 1 h and then 6 M HCl for 1 h. All solids were rinsed several times in DI water until the pH of the wash solution was neutral and they were dried in air at room temperature and weighed.

For comparison purposes, XC-72 carbon black powder was heated in an evacuated ampoule with phosphorus powder of the same P amount used as in 25-CoCl<sub>2</sub>/C reaction (annealed C/P) and without phosphorus (annealed C) at 500 °C for 48 hours.

#### Sample characterization

Powder X-ray diffraction (XRD) was performed using a Bruker D8 DaVinci diffractometer with nickel filtered Cu K $\alpha$  radiation, (40 kV, 40 mA, 0.05° step size, 5°–80° 2 $\theta$ ). Samples were ground to fine powders and affixed to glass slides using a thin layer of vacuum grease. XRD data for catalyst powders adhered to thin cut slabs of carbon-wax electrode tips before and after electrochemistry were obtained at higher resolution conditions (40 kV, 40 mA, 0.01° step size, 27°–60° 2 $\theta$ ). Reference XRD patterns were generated using Crystal Maker (<https://www.crystallmaker.com/index.html>). The elemental composition of thin pelletized samples was obtained using Rigaku ZSX Primus IV dispersive X-ray fluorescence spectrometer. The carbon content of the samples was further analyzed on a CE440 combustion CHN analyzer. Raman spectroscopy of the samples were performed on a Renishaw Raman microscope with a 514 nm excitation laser. The Brunauer–Emmett–Teller (BET) measurements (50-point isotherms) on Quantachrome Nova 1200 nitrogen surface area analyzer was performed on vacuum dried samples (150 °C for 4 hours). The morphology and elemental mapping of the samples were investigated using scanning electron microscopy (SEM) and energy dispersive spectroscopy (EDS) on a Hitachi S3400 system. Samples were prepared by pressing pre-ground samples onto carbon tape on aluminum stubs. The morphologies of the sonicated, methanol suspended particles were examined using a Hitachi S-7800 transmission electron microscope (TEM) with an accelerating voltage of 100 kV.

#### Electrode preparation

The various CoP<sub>3</sub> catalysts, 10% Pt on carbon, and annealed carbon black with and without phosphorus were evaluated using a graphite/carbon wax composite electrode described in our recent work.<sup>33,34,51,52</sup> Solid conducting graphite/carbon wax

electrodes are stable and inert with excellent reproducibility and negligible background current.<sup>53</sup> Several modifications for this current study are use of a 50/50 wt% graphite/carbon wax electrode composition and a PTFE liner that was coned at the electrode surface so that gas bubbles are more easily removed during electrocatalysis (Fig. S1, ESI†).<sup>34,51</sup>

The working electrode tips were formed by placing melted graphite/carbon wax into threaded and coned PTFE tubing (1.4 cm length, 3.2 mm ID, 6.4 mm OD) which has a 0.080 cm<sup>2</sup> geometric internal surface area. The blank 50% graphite/carbon wax ( $C_{\text{wax}}$ ) electrode tips were connected to 3.2 mm diameter brass current collectors, placed in a polyethylene bag, and submerged in a preheated (55 °C) water bath for ~10 minutes to soften the wax for catalyst embedment. About 1–2 mg of each catalyst sample was briefly sonicated to a homogeneous suspension with 20  $\mu\text{L}$  of methanol and about 5–10  $\mu\text{L}$  aliquot of this suspension was placed on an aluminum weigh boat. The aluminum weigh boat was allowed to air dry for several minutes and then its weight was tared in CAHN C-33 200 mg max microbalance, and it was then placed in a preheated hot plate (55 °C) for ~5 minutes. The coned surface of the warmed  $C_{\text{wax}}$  electrode tips was gently pressed onto the catalyst sample and excess powder adhered to PTFE tip surface was carefully returned to the aluminum weigh boat. The tip was re-pressed several times at a clean space inside the weigh boat to assure sample embedment. The aluminum weigh boat after catalyst loading was then weighed on the tared microbalance and the mass of catalyst loaded to electrode tip was recorded; typical sample mass loadings on the 0.08 cm<sup>2</sup>  $C_{\text{wax}}$  electrode tip ranged from about 0.5 to 1.0 mg.

### Electrochemical measurements

Electrochemical experiments utilized a three-electrode, single compartment cell, a Bioanalytical Systems (BASi) 100b potentiostat, and were guided by literature best practices.<sup>54</sup> The cell consisted of a PTFE covered Pyrex beaker, the modified BASi electrode-tip assembly described above as the working electrode, a saturated calomel reference electrode (SCE; Fisher Accumet), a platinum wire counter electrode, and a magnetic cross stir bar placed directly under the working electrode (~6 mm away) to aid gas removal from the electrode surface and minimize surface adhesion of gas bubbles. Graphite counter electrode was also used to verify that no platinum counter electrode effect is observed with these analyzed samples. Details of the experimental setup are similar to those described in our recent work and shown in Fig. S1 (ESI†).<sup>33,34,51</sup>

Hydrogen evolution reaction (HER) polarization curves were obtained using linear sweep voltammetry (LSV) at 5 mV s<sup>-1</sup> in acidic 0.5 M H<sub>2</sub>SO<sub>4</sub> (pH = 0.3) aqueous solutions. The electrolyte solutions were continually purged with H<sub>2</sub> (6.0 ultra-high purity 99.999%, Praxair) to maintain a reversible (H<sup>+</sup>/H<sub>2</sub>) Nernstian potential in the solution for HER reactions.<sup>55</sup> The SCE reference electrode was calibrated against reversible hydrogen electrode (RHE) values for the electrolyte solution using established conversions [ $E(\text{RHE}) = E(\text{SCE}) + 241 \text{ mV} + (59 \text{ mV}) \text{ pH}$ ]. RHE adjustment for 0.5 M H<sub>2</sub>SO<sub>4</sub> is 258.2 mV. All experimental

and literature potential values are reported *versus* RHE. All current densities are calculated using the geometric surface area of the graphite/carbon wax electrode (0.08 cm<sup>2</sup>). Typically for LSV in acidic media, 50 LSV scans with zero  $iR$  compensation and 20 LSV scans with 85%  $iR$  compensation were performed to verify reproducible sample responses and short-term sample stability. For  $iR$  uncompensated LSV scans, potential was swept to negative values until applied potentials of about -750 mV was reached and for 85%  $iR$  compensated LSV scans, the potential was swept to negative values until current density of about 50 mA cm<sup>-2</sup> is reached. Extended stability experiments of samples in 0.5 M H<sub>2</sub>SO<sub>4</sub> were analyzed by constant potential time base amperometry (chronoamperometry, CA) with the working electrode potential set at a value that produced ~10–15 mA cm<sup>-2</sup> current density during LSV experiments and held at that potential for 18 hours.

Electrochemical surface area (ECSA) measurements were obtained from double layer capacitance ( $C_{\text{dl}}$ ) values determined by cyclic voltammetry (CV), in the non-faradaic region (-100 mV to 350 mV RHE) in 0.5 M H<sub>2</sub>SO<sub>4</sub> at scan rates from 5 to 75 mV s<sup>-1</sup>. ECSA was calculated from the  $C_{\text{dl}}$  of each sample and the ideal specific capacitance ( $C_s$ , 35  $\mu\text{F cm}^{-2}$ ) of an atomically smooth planar electrode surface in 0.5 M H<sub>2</sub>SO<sub>4</sub>. Geometric electrode area is useful when catalytic surface reactions are limited by reactant transport, but ECSA may better account for the electroactive surface area of embedded electrocatalyst particles.

### Post electrochemical analysis

Approximately 1 mm of the surface of each catalyst loaded working electrode tips was cut for post electrochemical analysis and compared with similarly cut fresh catalyst loaded electrode tips. Powder XRD was done to examine the crystallinity of the catalysts before and after electrochemistry experiments. The PTFE lining of the electrode tips was removed, and the morphology and elemental analysis of the electrode tip surfaces were investigated using SEM/EDS and Raman spectroscopy.

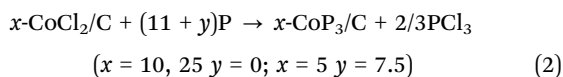

## Results and discussion

### Synthesis and structural analysis of CoP<sub>3</sub>/carbon black composites

Among the four Co–P binary phases (Co<sub>2</sub>P, CoP, CoP<sub>2</sub>, CoP<sub>3</sub>),<sup>56</sup> the most phosphorus rich phase is CoP<sub>3</sub>. We previously demonstrated that the solvent-free reaction of anhydrous CoCl<sub>2</sub> and stoichiometric amounts of elemental phosphorus produces crystalline phase pure CoP<sub>3</sub> at 500 °C along with volatile PCl<sub>3</sub> (eqn (1)).<sup>33,57</sup> In this study, we report a facile and flexible two-step synthetic approach for the growth of a series of CoP<sub>3</sub>/carbon composites. Different amounts of CoP<sub>3</sub> grown on carbon black powder ( $x\text{-CoP}_3/\text{C}$ ,  $x = 5, 10, 25 \text{ mol}\%$ ) samples were produced from methanol deposition of  $x \text{ mol}\%$  of CoCl<sub>2</sub> onto carbon black ( $x\text{-CoCl}_2/\text{C}$ ) followed by metal phosphide formation through solvent-free, direct reaction of  $x\text{-CoCl}_2/\text{C}$  with P<sub>4</sub> vapor at 500 °C. The balanced reactions for CoP<sub>3</sub> and  $x\text{-CoP}_3/\text{C}$  synthesis are shown in eqn (1) and (2). The reaction of CoCl<sub>2</sub> with

phosphorus is thermodynamically driven *via* volatile  $\text{PCl}_3$  elimination ( $\Delta H_f = -320 \text{ kJ mol}^{-1}$ ).

The methanol dissolution step to form  $x\text{-CoCl}_2/\text{C}$  produced purple-colored solutions with a carbon black slurry and slow evaporation of methanol under vacuum resulted in precipitation of  $\text{CoCl}_2$  onto carbon black. After drying they were black powders with no visible purple  $\text{CoCl}_2$ -rich regions and recovered powders were greater than 90% of the total reagent weight. Distinct XRD peaks for  $\text{CoCl}_2$  in a carbon black matrix were identified in 25- $\text{CoCl}_2/\text{C}$  (Fig. S2, ESI<sup>†</sup>), which indicates the successful  $\text{CoCl}_2$  deposition on carbon black *via* methanol precipitation. A schematic of the  $x\text{-CoCl}_2/\text{C}$  process is shown in step 1 of Fig. 1.

In contrast to our prior  $\text{CoP}_3$  synthesis (eqn (1)), analogous experiments with  $x\text{-CoCl}_2/\text{C}$  and stoichiometric amounts of red phosphorus produced lower Co-P products. It was determined that excess phosphorus was needed for phase pure  $\text{CoP}_3$  formation from  $x\text{-CoCl}_2/\text{C}$ . Excess phosphorus in the range of 3–5 times more than stoichiometric amounts led to  $\text{CoP}_3$  growth on carbon black powder, specifically three-fold excess phosphorus was sufficient for 10- $\text{CoP}_3/\text{C}$  and 25- $\text{CoP}_3/\text{C}$ , while five-fold excess phosphorus was needed for the lowest  $\text{CoCl}_2$  content 5- $\text{CoP}_3/\text{C}$  composite (eqn (2)). When the 5- $\text{CoP}_3/\text{C}$  targeted reaction was run using a lower three-fold excess of phosphorus, XRD showed multiple phases were produced, including  $\text{CoP}$ ,  $\text{CoP}_2$  and  $\text{CoP}_3$  (Fig. S3, ESI<sup>†</sup>). XRD data for successful single phase  $\text{CoP}_3$  alone and supported on carbon black ( $x\text{-CoP}_3/\text{C}$ ) are shown in Fig. 2. All the XRD patterns of free standing  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  ( $x = 5, 10, 25$ ) match with the crystalline cubic, skutterudite-type  $\text{CoP}_3$  structure [space group =  $Im\bar{3} (204)$ ], consistent with the  $\text{CoP}_3$  reference pattern (PDF#01-070-6854). The annealed carbon black reacted with P (annealed C/P) at 500 °C is also shown.

The  $\text{CoP}_3$  peak intensities increase in  $x\text{-CoP}_3/\text{C}$  composites as the amount of  $\text{CoP}_3$  on the carbon black support increases. As the content of  $\text{CoP}_3$  in the composites decreases to 5 mol%, diffraction intensity from  $\text{CoP}_3$  is reduced, but crystalline  $\text{CoP}_3$  is still visible in

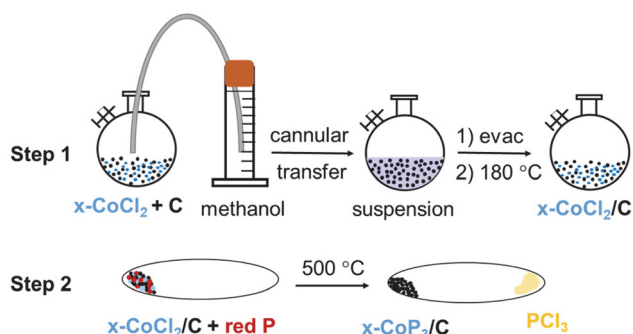

Fig. 1 Schematic of two-step synthesis procedure of  $x\text{-CoP}_3/\text{C}$  ( $x = 5, 10, 25$  mol%) materials. Step 1 shows methanol precipitation of  $\text{CoCl}_2$  onto C (XC-72 carbon black), and step 2 shows direct reaction of  $x\text{-CoCl}_2/\text{C}$  with elemental red phosphorus at 500 °C.

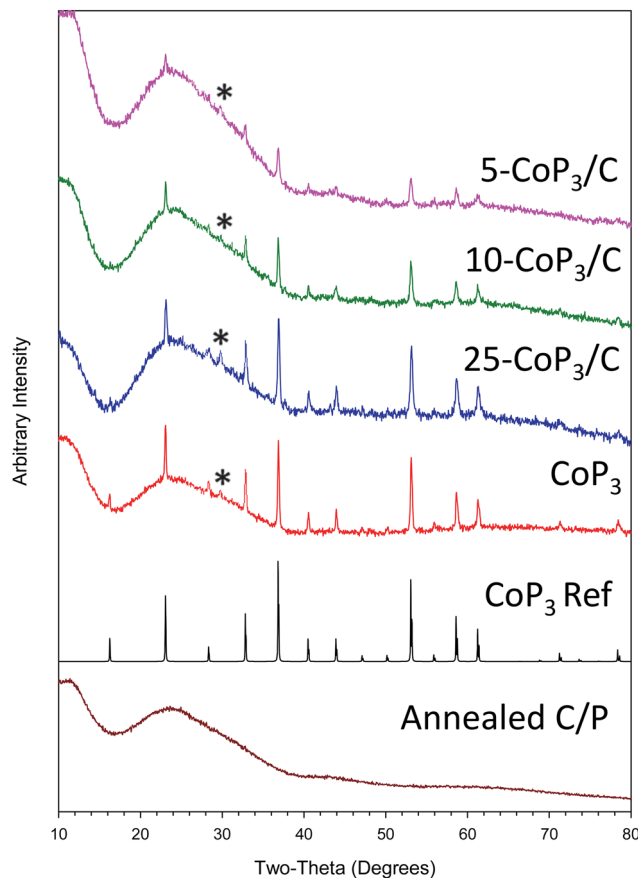

Fig. 2 Powder XRD results for  $x\text{-CoP}_3/\text{C}$  ( $x = 5, 10, 25$  mol%) products from two-step synthesis procedure of methanol precipitations of  $x\text{-CoCl}_2/\text{C}$  ( $x = 5, 10, 25$  mol%) followed by direct reactions of  $x\text{-CoCl}_2/\text{C}$  with elemental red phosphorus at 500 °C. Reference (Ref) pattern for  $\text{CoP}_3$  and XC-72 carbon black annealed at 500 °C with elemental red phosphorus are also shown. Trace  $\text{CoP}_2\text{O}_6$  impurity are identified with a (\*).

the XRD pattern. Estimated crystallite sizes using XRD peak widths show that carbon black supported  $\text{CoP}_3$  crystallites are relatively smaller in size compared to bulk  $\text{CoP}_3$  indicating that some particle size reduction for crystallites grown on carbon black (Table 1). Traces of  $\text{CoP}_2\text{O}_6$  (PDF#04-010-2428) were observed in both free standing  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  composites. This phosphite might result from phosphorus reaction with some oxygen containing species adsorbed on carbon black and/or  $\text{CoCl}_2$  particles. Adsorbed water or methanol during the  $\text{CoCl}_2$  deposition process may be an oxygen source.

During synthesis, some reaction is evident by 250 °C when the  $\text{CoCl}_2/\text{P}$  powder mixture turns black and red phosphorus starts to sublime to gaseous  $\text{P}_4$  as the reaction temperature approaches 500 °C. Subsequent heating at 500 °C results in  $\text{CoP}_3$  crystallite growth and a colorless, volatile  $\text{PCl}_3$  byproduct, previously confirmed by  $^{31}\text{P}$  NMR.<sup>57</sup> The pH of the transported  $\text{PCl}_3$  for the  $x\text{-CoP}_3/\text{C}$  reactions tested immediately after opening the reaction tube showed similar acidity to phosphoric acid, so acidic  $\text{H}_x\text{PO}_3\text{Cl}_2$  species may form during synthesis and give rise to trace phosphite impurities. Both free-standing  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  composite products were isolated as black solids with crystalline  $\text{CoP}_3$  and greater than 75% yields (Table 1).

**Table 1** Summary of experimental and characterization results for  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  products

CoCl <sub>2</sub> /P reactant molar ratio (target $\times$ mol% $\text{CoP}_3$ for $x\text{-CoP}_3/\text{C}$ )	XRD phase <sup>a</sup> (cryst. size, nm)	Yield <sup>b</sup> (%)	XRF Co:P molar ratios	XRF/CHN Co:C molar ratio (ideal)	BET surface area <sup>c</sup> ( $\text{m}^2 \text{g}^{-1}$ )
1/3.7 ( $\text{CoP}_3$ )	$\text{CoP}_3$ (44)	77	1:3.00	Not applicable	3
1/11.1 (25- $\text{CoP}_3/\text{C}$ )	$\text{CoP}_3$ (34)	76	1:2.65	1:2.4/3.1 (1:3.0)	11
1/11.0 (10- $\text{CoP}_3/\text{C}$ )	$\text{CoP}_3$ (35)	79	1:2.82	1:5.6/6.5 (1:9.0)	17
1/18.5 (5- $\text{CoP}_3/\text{C}$ )	$\text{CoP}_3$ (34)	89	1:3.00	1:13.5/17.0 (1:19.0)	35

<sup>a</sup> Crystallite size from XRD peak width, trace  $\text{CoP}_2\text{O}_6$  peaks detected. <sup>b</sup> Yield based on target composition and product mass. <sup>c</sup> BET values for annealed C ( $238 \text{ m}^2 \text{g}^{-1}$ ) and annealed C/P ( $37 \text{ m}^2 \text{g}^{-1}$ ).

Control experiments annealing only carbon black at  $500^\circ\text{C}$  results in near quantitative recovery of carbon (annealed C). The recovered yield of carbon black annealed with phosphorus was slightly greater than ( $\sim 110\%$ ) annealed carbon black yield indicating that carbon black incorporates some phosphorus at elevated temperatures (annealed C/P), while maintaining its amorphous structure (Fig. 2). The broad and low intensity XRD peaks centered at  $23.5^\circ$  and  $43.2^\circ$  are in the same positions as disordered carbon black and near interplanar graphite spacings (Fig. S4, ESI<sup>†</sup>) so no clear structural differences occur in the carbon support when heated with phosphorus.

The presence of both  $\text{CoP}_3$  and disordered/graphitic carbon in the  $x\text{-CoP}_3/\text{C}$  composites was examined using Raman spectroscopy. The Raman spectra of synthesized crystalline  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  materials is shown in Fig. 3 and Fig. S5 (ESI<sup>†</sup>). Both annealed carbon black samples with or without excess phosphorus and all  $x\text{-CoP}_3/\text{C}$  composites show two peaks centered at approximately  $1570\text{--}1578 \text{ cm}^{-1}$  and  $1332\text{--}1342 \text{ cm}^{-1}$ , which correspond to carbon bonding vibrations for graphitic (G-band) and disordered (D-band) structures, respectively.<sup>58–60</sup> Consistent with the prior studies, eight active Raman modes for skutterudite  $\text{CoP}_3$  structure ( $\Gamma_{\text{R}} = 2A_{\text{g}} + 2E_{\text{g}} + 4T_{\text{g}}$ ) was observed in  $\text{CoP}_3$  and 25- $\text{CoP}_3/\text{C}$  composite materials.<sup>40</sup> These  $\text{CoP}_3$  peaks were still present but not well resolved in 10- $\text{CoP}_3/\text{C}$  and 5- $\text{CoP}_3/\text{C}$  samples probably due to lower  $\text{CoP}_3$  content in the carbon matrix. Several weak intensity peaks between  $650 \text{ cm}^{-1}$  to  $1130 \text{ cm}^{-1}$  for  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  composites may correspond to P–O bonding in anionic structures consistent with XRD evidence for  $\text{CoP}_2\text{O}_6$ .<sup>61–65</sup> The Raman results provide further support for crystalline  $\text{CoP}_3$  growth on carbon black for the  $x\text{-CoP}_3/\text{C}$  composite structures.

### Compositional analysis of $x\text{-CoP}_3/\text{C}$ composites

According to XRF analyses, free standing  $\text{CoP}_3$  and the  $x\text{-CoP}_3/\text{C}$  composite powders have relative atomic compositions consistent with  $\text{CoP}_3$  (Table 1). The Co:C molar ratios for  $x\text{-CoP}_3/\text{C}$  composites obtained from both XRF and CHN analysis indicate that carbon content is slightly lower than the ideal ratios but shows the expected increase in carbon content with decreasing  $\text{CoP}_3$  amounts. The EDS mapping for elements in free standing  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  powders is shown in Fig. S6 and S7 (ESI<sup>†</sup>). The elemental maps for all  $x\text{-CoP}_3/\text{C}$  samples show homogeneous distributions of the elements and relatively intense P signals consistent with  $\text{CoP}_3$  in these materials. As expected, the carbon signal shows increased intensity as  $\text{CoP}_3$  content decreases. A homogenous distribution of phosphorus and carbon

**Fig. 3** An overlay of Raman spectra of  $\text{CoP}_3$ ,  $x\text{-CoP}_3/\text{C}$  ( $x = 5, 10, 25$ ) and  $500^\circ\text{C}$  annealed carbon black alone (C) and carbon black annealed with phosphorus (C/P) in the region of  $200\text{--}2000 \text{ cm}^{-1}$ . (◆) denotes peaks for P–O bonding.

is observed in the annealed C/P sample (Fig. S8, ESI<sup>†</sup>) and EDS analysis estimates indicate about 2 mol% P in the carbon material. The bulk CHN analysis of annealed C is 99.6 wt% C, while annealed C/P samples are 78.9 wt% C, leading to an upper estimate of  $\sim 9 \text{ mol}\%$  phosphorus in annealed C/P, though some of this non-carbon sample mass includes oxygen content.

### Microstructural and morphological analysis of $x\text{-CoP}_3/\text{C}$ composites

Consistent with our prior work on free-standing  $\text{CoP}_3$  particle growth,<sup>33</sup> the morphology of  $\text{CoP}_3$  from scanning electron microscopy (SEM) shows it consists of a collection of large

~300–500  $\mu\text{m}$  shard-like aggregates comprised of smaller fused, bead-like, faceted microparticles of about 0.5  $\mu\text{m}$  in size (Fig. 4). In contrast, the  $x\text{-CoP}_3/\text{C}$  composites form as relatively smaller, loosely packed aggregates of fused, irregular particles. The 25- $\text{CoP}_3/\text{C}$  sample consists of ~20–50  $\mu\text{m}$  sized, faceted aggregates of irregular fused particles ranging from 1  $\mu\text{m}$  to 5  $\mu\text{m}$  in size. Smaller particle aggregates of about 5–10  $\mu\text{m}$  are identified in 10- $\text{CoP}_3/\text{C}$  and 5- $\text{CoP}_3/\text{C}$  products, indicating that the particle aggregate size is gradually reduced as the carbon black content in the composite increases.

The annealed C control sample is comprised of spherical nanoparticle mixtures of ~10–25 nm size and ~50–60 nm size particles by TEM (Fig. 5). The annealed C/P particles are a slightly larger mix of ~15–30 nm and ~50–100 nm sizes. The TEM images for  $x\text{-CoP}_3/\text{C}$  represent the smaller particulate components of fused particle aggregates of  $x\text{-CoP}_3/\text{C}$  identified by SEM. Some of the observed nanoparticle sizes and morphologies in the  $x\text{-CoP}_3/\text{C}$  composites resemble the annealed carbon black products. Given that our two-step synthesis first involves deposition of  $\text{CoCl}_2$  crystallites onto carbon black powder, it is

Fig. 4 Representative SEM images of  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  ( $x = 5, 10, 25$  mol%) powders from reactions of  $x\text{-CoCl}_2/\text{C}$  and red phosphorus at 500  $^\circ\text{C}$ . Scale bars are 50  $\mu\text{m}$  for all left images. Scale bar lengths for right images of  $\text{CoP}_3$  and 10- $\text{CoP}_3/\text{C}$  are 5  $\mu\text{m}$  and 25- $\text{CoP}_3/\text{C}$  and 5- $\text{CoP}_3/\text{C}$  are 10  $\mu\text{m}$ .

Fig. 5 Representative TEM images of  $x\text{-CoP}_3/\text{C}$  ( $x = 5, 10, 25$  mol%) particles and aggregates synthesized from direct reactions of  $x\text{-CoCl}_2/\text{C}$  ( $x = 5, 10, 25$  mol%) with elemental red phosphorus at 500  $^\circ\text{C}$ .

anticipated that the  $\text{CoP}_3$  crystallites are well mixed with carbon black. In general, these composites have roughly spherical semi-transparent carbon black nanoparticle (~10 nm to 50 nm) interspersed with darker, sometimes larger, faceted particles (~50–150 nm) that are likely crystalline cubic  $\text{CoP}_3$  (Fig. 5). There were no clear differences in the particle sizes, morphologies, and aggregation between the different composites, but the prevalence of darker faceted particles that are likely  $\text{CoP}_3$  crystallites increases from 5 mol% to 25 mol% in carbon composites. The SEM and TEM images are consistent with  $\text{CoP}_3$  crystallites growing from  $\text{CoCl}_2$  crystallites deposited on carbon black nanoparticles to form into well-mixed composite structures. The nanoscale carbon black features and variations in morphological features may lead to differences in external surface areas of different composite structures.

The particle aggregation shown by SEM is reflected in changes in BET surface areas from nitrogen adsorption measurements (Table 1). The full adsorption/desorption nitrogen isotherms for  $\text{CoP}_3$ ,  $x\text{-CoP}_3/\text{C}$  and annealed carbon black samples are shown in Fig. S9 (ESI<sup>†</sup>). No significant change in BET surface area was observed between XC-72 carbon black (~250  $\text{m}^2 \text{g}^{-1}$ )<sup>66–68</sup> and our 500  $^\circ\text{C}$  annealed C powder (238  $\text{m}^2 \text{g}^{-1}$ ). Some studies have shown that phosphorus doping in carbon structures can increase surface area, pore volume and average pore sizes.<sup>69</sup> In contrast, carbon black particle growth or aggregation occurs in our annealed C/P as its 37  $\text{m}^2 \text{g}^{-1}$  surface area is ~6 times lower than annealed C. The measured surface area of 5- $\text{CoP}_3/\text{C}$  is similar to annealed C/P, and as  $\text{CoP}_3$  content increases to 10 and 25 mol%, surface area decreases from ~35 to 11  $\text{m}^2 \text{g}^{-1}$ , which is still nearly 4 to 10 times larger than the bulk  $\text{CoP}_3$  surface area (~3  $\text{m}^2 \text{g}^{-1}$ ). The decrease in BET surface area with increasing  $\text{CoP}_3$  content is consistent with observed increased particle aggregation in SEM/TEM images (Fig. 4). A similar trend of reduced surface area was

reported for a carbon supported FeP catalyst composite.<sup>39</sup> These surface area results show that the high surface area carbon black powder can improve the overall external surface area and likely the dispersion of CoP<sub>3</sub> in the composite structure.

### Examination of the HER activity of *x*-CoP<sub>3</sub>/C composite materials

The relative electrocatalytic HER performance of *x*-CoP<sub>3</sub>/C powders directly adhered to sticky carbon wax (C<sub>wax</sub>) composite electrode tips was evaluated in a three-electrode cell in H<sub>2</sub>-saturated 0.5 M H<sub>2</sub>SO<sub>4</sub>, similar to our recent studies.<sup>33,34,51,52</sup> The HER activity and stability of the catalysts were examined using linear sweep voltammetry (LSV) and constant potential time base chronoamperometry (CA) measurements, respectively. Representative *iR* uncompensated LSV scans for free standing CoP<sub>3</sub> and *x*-CoP<sub>3</sub>/C samples are shown in Fig. 6. The individual LSV and CA data for CoP<sub>3</sub> and *x*-CoP<sub>3</sub>/C composites

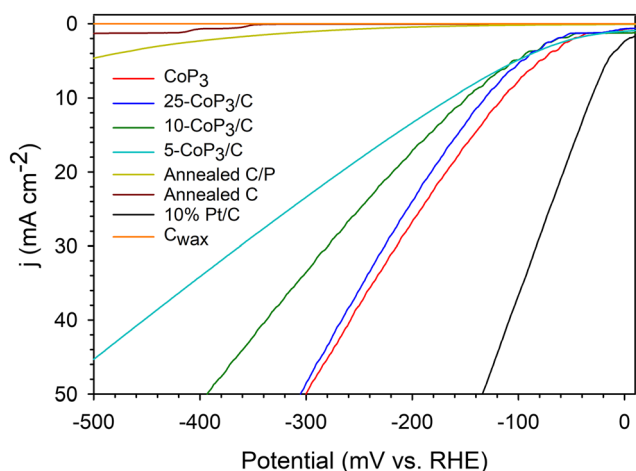

Fig. 6 Representative LSV data for *x*-CoP<sub>3</sub>/C (*x* = 5, 10, 25 mol%) powders on C<sub>wax</sub> electrodes using Pt counter and SCE reference electrodes in 0.5 M H<sub>2</sub>SO<sub>4</sub> (5 mV s<sup>-1</sup> scan rate, no *iR* compensation) in a three-electrode cell. An LSV overlay graph with 85% *iR* compensated data is shown in Fig. S15 (ESI<sup>†</sup>). Plots for C<sub>wax</sub>, annealed C, annealed C/P and commercial 10% Pt/C are shown for comparison.

is shown in Fig. S10–S14 and S18, S19 (ESI<sup>†</sup>). An LSV overlay plot with 85% *iR* compensated data is shown in Fig. S15 (ESI<sup>†</sup>). The *iR* compensated average applied potentials to achieve 10 mA cm<sup>-2</sup> current densities are about 40–60 mV lower than the uncompensated results. Table 2 shows a summary of average LSV data, average Tafel slopes near onset potentials, electrochemically active surface area (ECSA) measurements and percent current density retained after 18 h CA experiments.

Very low to negligible HER activity is observed for both annealed C and annealed C/P powders, with a slight catalytic improvement for the annealed-C/P at high applied potentials. This contrasts with several prior studies on phosphorus-doped carbons that show moderate improvement in ORR and HER activity *versus* carbon.<sup>47,69</sup> Similarly, nitrogen-doped carbon materials can show enhanced HER catalytic activity.<sup>23,48,60</sup> In contrast to annealed C/P materials, HER activity is greatly improved once CoP<sub>3</sub> is introduced onto the carbon support and all *x*-CoP<sub>3</sub>/C composites show higher HER activity approaching the activity of CoP<sub>3</sub> particles that require an applied potential of -115 mV to reach a 10 mA cm<sup>-2</sup> current density (Fig. 6 and Table 2). The HER activity of free standing and composite catalysts followed the trend of 5-CoP<sub>3</sub>/C < 10-CoP<sub>3</sub>/C < 25-CoP<sub>3</sub>/C ≤ CoP<sub>3</sub> for applied potentials required to achieve 10 mA cm<sup>-2</sup> current density. This overall activity trend follows changes in CoP<sub>3</sub> content in the composite, but the changes are relatively small *versus* the decrease in relative molar/atomic CoP<sub>3</sub> content to as low as 5 mol%. While the unsupported CoP<sub>3</sub> catalyst achieves 10 mA cm<sup>-2</sup> current density at -114 mV, the more dilute 5-CoP<sub>3</sub>/C sample (CoP<sub>3</sub> : C atomic ratio of 1 : 20) generates about 6 mA cm<sup>-2</sup> at this potential. With *iR* corrections, there is only a ~20 mV difference in activity of bulk CoP<sub>3</sub> *versus* any of the *x*-CoP<sub>3</sub>/C carbon composite materials (Table 2).

The 25-CoP<sub>3</sub>/C composite catalyst showed most similar HER performance to free standing CoP<sub>3</sub> particles but with only 25 mol% CoP<sub>3</sub> content (CoP<sub>3</sub> : C ratio of 1 : 4). When an 85% *iR* correction (cell resistance) is applied, 25-CoP<sub>3</sub>/C (~40 Ω) outperformed pure CoP<sub>3</sub> (~35 Ω) at applied potentials beyond -150 mV (Fig. S15, ESI<sup>†</sup>), so lower amounts of CoP<sub>3</sub> distributed on conducting carbon particles have similar activity to pure CoP<sub>3</sub>. The similar electrochemical cell resistances suggest that

carbon black powder does not interfere with electrical conduction or catalyst surface charge transfer during the electrochemical reactions. There surface charge accumulation abilities of  $\text{CoP}_3$  and all  $x\text{-CoP}_3/\text{C}$  composites are similar to a commercial 10%Pt/C standard and much higher than carbon support values (Table 2). The ECSA values derived from cyclic voltammetry data are near  $45 \text{ cm}^2$  for all  $\text{CoP}_3$  samples and much larger than the near  $1 \text{ cm}^2$  values for the carbon supports (Fig. S16 and S17, ESI<sup>†</sup>). A previous study showed a similar increase in ECSA when 50 wt% FeP was loaded onto carbon particulate supports.<sup>39</sup> For comparison,  $\text{CoP}_3$  nanoparticles synthesized *via* a hydrothermal-phosphidation approach reportedly have a high capacitance of  $44.6 \text{ mF cm}^{-2}$  (converted ECSA of  $319 \text{ cm}^2$ ).<sup>40</sup> In our work, the similarity in ECSA values for all  $x\text{-CoP}_3/\text{C}$  composites and bulk  $\text{CoP}_3$  is reflected in their similar HER activity and it contrasts with their large differences in physical BET surface area. Plots of BET *versus* ECSA values for  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  are shown in Fig. 7 along with a bar graph of applied potentials needed to achieve  $10 \text{ mA cm}^{-2}$  current densities. While the carbon black support provides surface area advantages, it appears that its major influence is

to distribute the lower amounts of electroactive  $\text{CoP}_3$  effectively along its conducting particulate structure and facilitate electron transfer from the  $\text{C}_{\text{wax}}$  electrode and the electrolyte solution. The moderate physical BET surface area of the composites with lower  $\text{CoP}_3$  content and higher ECSA values, suggests that lower amounts of supported  $\text{CoP}_3$  are distributed on the carbon support in a manner that leads to similar amounts of electrochemically active surfaces exposed to the acidic electrolyte as compared to bulk  $\text{CoP}_3$ .

The calculated Tafel slopes related to  $\text{H}_2$  formation kinetics at initial LSV current flow, show similar trends to the HER activity that slightly decreases with decreasing  $\text{CoP}_3$  content. The Tafel value for  $\text{CoP}_3$  is near that of the Pt/C standard and similar to prior work in  $\text{CoP}_3$  nanoparticles ( $-58 \text{ mV dec}^{-1}$ ).<sup>40</sup> The Tafel slopes increase from  $\text{CoP}_3$  through the  $x\text{-CoP}_3/\text{C}$  composite as  $\text{CoP}_3$  content decreases. There Tafel slopes near  $100\text{--}120 \text{ mV dec}^{-1}$ , for both free standing and  $x\text{-CoP}_3/\text{C}$  composites are consistent with mixed Volmer–Tafel or Volmer–Heyrovsky mechanisms for proton reduction.<sup>70</sup> The larger Tafel slopes at low  $\text{CoP}_3$  content in the composites indicate an expected lower rate of surface proton reduction with high carbon content and fewer electroactive  $\text{CoP}_3$  surface sites.

All the  $\text{CoP}_3$  based electrocatalyst materials ( $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$ ) showed  $>92\%$  percent retention of  $\sim 10\text{--}15 \text{ mA cm}^{-2}$  current density at a constant applied potentials (CA, Table 2) and LSV scans obtained after 18 h CA measurements overlay well with the initial scans. The CA results show that both phosphorus rich  $\text{CoP}_3$  and supported particulates are more robust in corrosive acidic HER environments than the Pt/C standard (Fig. S18 and S19, ESI<sup>†</sup>). These results agree well with stability observed for  $\text{CoP}_3$  nanoparticles and supported  $\text{CoP}_3$ .<sup>40</sup> The extended stability of  $\text{CoP}_3$  and the  $x\text{-CoP}_3/\text{C}$  composites may be due to the chemically robust nature of  $\text{CoP}_3$  (resists dissolution in 6 M HCl) and the presence of  $[\text{P}_4]^{4-}$  polyphosphide anions that may stabilize the catalyst surface during HER.<sup>71</sup> Polyphosphides may also protect metal cations from dissolution and the formation of P–H surface bonds can contribute to the reduction process. Some theoretical studies suggest P-rich phosphide HER mechanisms may rely on non-metal surface hydrogen bonds.<sup>18,25</sup>

After the extended CA experiments, the electrode tips ( $\text{C}_{\text{wax}}$  with catalyst particles embedded on its surface) were directly examined by XRD, SEM/EDS, and Raman analysis to verify retention of the crystalline  $\text{CoP}_3$  catalyst. Powder XRD results show that crystalline  $\text{CoP}_3$  is present on electrode tips of  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  composites after extended CA experiments (Fig. S20 and S21, ESI<sup>†</sup>). SEM images show evidence of particle surface roughening, a decrease in particle aggregation, and some smoother edges on larger  $\text{CoP}_3$  crystallites (Fig. S22, ESI<sup>†</sup>). The low  $\text{CoP}_3$  content catalysts were more difficult to distinguish as some may be embedded in the  $\text{C}_{\text{wax}}$  surface. The near surface elemental distribution for  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  particles on  $\text{C}_{\text{wax}}$  electrodes before and after CA measurements was examined by EDS mapping. A homogenous distribution of Co and P was observed across the sample and a more intense P signal indicates the survival of phosphorus rich  $\text{CoP}_3$  structures after the 18 h CA experiments (Fig. S23 and S24, ESI<sup>†</sup>). In some

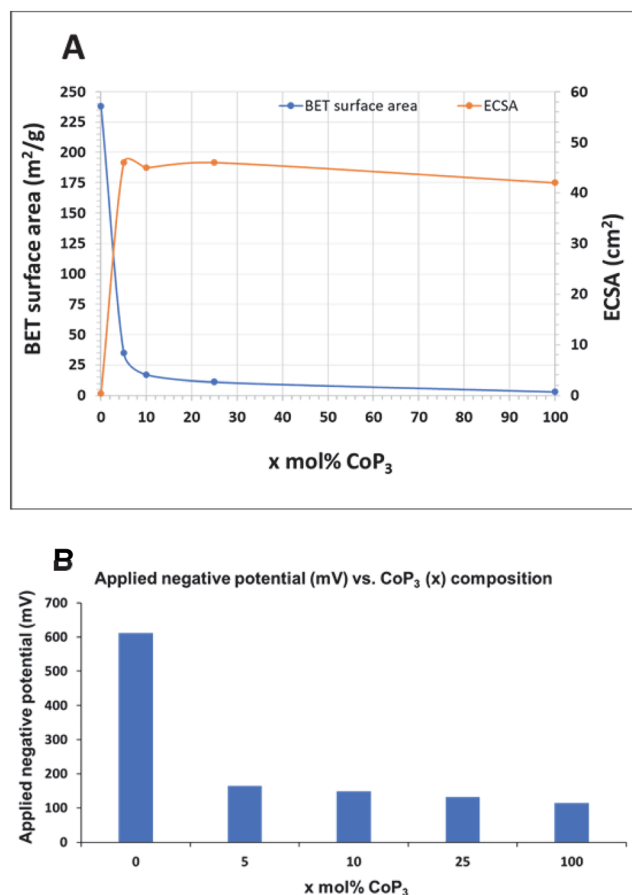

Fig. 7 (A) Comparison of trends of physical BET surface area and electrochemically active surface area (ECSA) for  $\text{CoP}_3$  and  $x\text{-CoP}_3/\text{C}$  ( $x = 5, 10, 25 \text{ mol}\%$ ) materials along with annealed C/P ( $x = 0$ ). (B) Variation of applied negative potentials (*iR* uncompensated) to achieve a  $10 \text{ mA cm}^{-2}$  current density with the amount of  $\text{CoP}_3$  dispersed on carbon black composites.

cases, the carbon intensity increases after CA experiments, which may be due to catalyst loss or catalyst being embedded deeper in the carbon wax. As expected, there are more prominent oxygen surface signals after extended catalysis experiment. Surface oxidation after long term HER electrocatalysis have been frequently observed with electrocatalysts.<sup>72,73</sup> Surface phosphates could form in the acidic aqueous environment and estimated surface compositions show slightly lower phosphorus and higher oxygen contents for the post electrocatalysis electrode surfaces (Table S1, ESI†).

Raman spectra were obtained for CoP<sub>3</sub> and *x*-CoP<sub>3</sub>/C powders on C<sub>wax</sub> electrodes before and after CA experiments (Fig. S25 and S26, ESI†). Due to sensitivity issues with the low CoP<sub>3</sub> amounts on the C<sub>wax</sub> surface for 10-CoP<sub>3</sub>/C and 5-CoP<sub>3</sub>/C, only the carbon/graphite peaks were observed for these samples. Similar to the bulk Raman results (Fig. 3), peaks for graphite/disordered carbon and CoP<sub>3</sub> are observed before and after extended CA experiments for both CoP<sub>3</sub> and 25-CoP<sub>3</sub>/C on the C<sub>wax</sub> electrodes. The CoP<sub>3</sub> peak intensities vary relative to the carbon signal but there is no visible increase in P-O vibrations after the CA experiments.

Due their relative ease in synthesis, metal-rich and monophosphides are more frequently examined as earth-abundant HER catalyst alternatives to Pt/C materials. Relatively few phosphorus-rich metal phosphides and composites have been studied for electrocatalytic HER, but some have shown HER activity in 0.5 M H<sub>2</sub>SO<sub>4</sub> similar to a 10% Pt/C catalyst (Table S2, ESI†). A crystalline 3D porous CoP<sub>3</sub> nanoneedle array on carbon fiber paper (CFP) was produced by hydrothermal precursor decomposition followed by phosphidation using red phosphorus at elevated temperatures (750 °C) that shows impressive HER activity to produce 10 mA cm<sup>-2</sup> current densities at low overpotentials of -126 mV (*vs.* RHE),<sup>40</sup> which is comparable to our free standing CoP<sub>3</sub> microparticles. Porous CoP<sub>3</sub> concave polyhedrons deposited on carbon fiber paper (CFP) show enhanced HER activity *versus* CoP<sub>3</sub> nanoparticles and produces 10 mA cm<sup>-2</sup> current densities at low overpotentials of -78 mV.<sup>32</sup> Similarly impressive acidic electrolyte activity and stability was achieved for RhP<sub>2</sub> grown on a nanocarbon support.<sup>47</sup>

These synthetic results described here for *x*-CoP<sub>3</sub>/C composites shows the tunability of our solvent-free, direct reactions to deposit varying amounts of phosphorus-rich CoP<sub>3</sub> onto carbon black powder surfaces at moderate 500 °C temperatures using less-exotic reactants than typical PH<sub>3</sub> based syntheses. The produced *x*-CoP<sub>3</sub>/C composites show systematic behavior expected for structures where reduced catalyst loading is balanced with improved catalyst dispersion across the carbon support. This leads to similar ECSA values and slightly reduced catalytic activities for relatively low CoP<sub>3</sub> content materials (*e.g.* 10 mol% CoP<sub>3</sub> on carbon black) *versus* the free standing CoP<sub>3</sub> microparticle aggregates. The CoP<sub>3</sub> grown in a dispersed fashion on carbon black is more active for HER on a catalyst mass basis, but the crystalline domains of carbon supported CoP<sub>3</sub> are only about 20% smaller than those for free standing CoP<sub>3</sub>. When considering *iR* corrections to the HER data, the different *x*-CoP<sub>3</sub>/C all achieve 10 mA cm<sup>-2</sup> current densities near -95 mV

(Table 2 and Fig. S15, ESI†). The lower stability of the 10%Pt/C standard *versus* *x*-CoP<sub>3</sub>/C composites is notable, as metals such as platinum deposited on carbon black powders are found to be easily subjected to agglomeration and/or migration of the metal on the carbon surface.<sup>69</sup> The electrocatalytic stability of the *x*-CoP<sub>3</sub>/C structures suggests a robust connection of the CoP<sub>3</sub> crystallites directly grown interspersed with carbon black particles. Other studies have observed benefits from phosphorus-doped carbon supports improving HER activity and stability of a catalyst loaded onto these carbon surfaces, which may be present in the current materials.<sup>48,60</sup>

## Conclusions

A two-step synthetic method involving CoCl<sub>2</sub> deposited on carbon black followed by its solid-state reaction with elemental phosphorus vapor, yields a tunable range of CoP<sub>3</sub>/C composite structures. Several compositions from 5–25 mol% CoP<sub>3</sub> were produced and structurally and compositionally characterized. Crystalline aggregates of CoP<sub>3</sub> with small ~35 nm crystallite sizes are homogeneously distributed on the carbon black. All composites showed HER activity near that of CoP<sub>3</sub>, and they achieved a 10 mA cm<sup>-2</sup> current density with a similar applied potential near -95 mV (*iR* compensated) despite containing much lower CoP<sub>3</sub> catalyst content. Their good retention of extended HER activity showed that the composite structures are stable in an acidic electrolyte. This study shows the success in adapting and extending direct MCl<sub>2</sub>/P reactions that form crystalline metal phosphides to more complex supported materials.<sup>33,34,51</sup> This synthetic extension should be applicable different particulate supports and other crystalline metal phosphide catalysts using 3d earth abundant metals. Beyond HER electrocatalysis, CoP<sub>3</sub> crystallites or related phosphides distributed on conducting carbon supports may find use in battery electrodes and capacitors,<sup>74</sup> or other electrocatalytic transformations such as nitrogen reduction.<sup>75</sup>

## Author contributions

Conceptualization and methodology (IL and EG); formal analysis and visualization (IL and EG), investigation (IL and HB), writing and editing (IL and EG); supervision and project administration (EG).

## Conflicts of interest

There are no conflicts to declare.

## Acknowledgements

The authors gratefully thank Matthew Lovander for preliminary electrochemical analysis and assistance with carbon-wax electrode designs and gratefully acknowledge funding support from a U.S. National Science Foundation (Division of Chemistry, grant 1954676) and the University of Iowa. H. B.

acknowledges a U.S. National Science Foundation grant (1757548) for the summer research experience for undergraduates (REU) program at the University of Iowa. Staff in the UI MatFab (K. Horkley and D. Unruh) and Central Microscopy Research Facility (J. Shao) are thanked for assistance with XRF, Raman spectroscopy and TEM.
