Semiconductor-based photocatalysts for photocatalytic and photoelectrochemical water splitting: will we stop with photocorrosion?

Sha Chen,^{ab} Danlian Huang,^{ID} *^{ab} Piao Xu,^{ab} Wenjing Xue,^{ab} Lei Lei,^{ab} Min Cheng,^{ab} Rongzhong Wang,^{ab} Xigui Liu^{ab} and Rui Deng^{ab}

The status of photocatalytic (PC)/photoelectrochemical (PEC) water splitting as a promising approach to solar-to-chemical energy conversion has increased significantly over the past several decades for addressing the energy shortage. However, the overall energy conversion efficiency is still relatively poor due to the severe photocorrosion in photosensitive semiconductors. Herein, the review begins with the discussion of the photocorrosion mechanism with several typical semiconductors as examples. Then the feasible characterization methods used to evaluate the stability of semiconductors are summarized. Notably, most studies regarding water splitting focus on achieving high efficiency by improving the charge separation and transfer efficiency within the semiconductors. This review focuses on the recent advances in effective strategies for photocorrosion inhibition of semiconductor-based composites with respect to their intrinsic properties and interface charge transfer kinetics, including morphology/size control, heteroatom doping, heterojunction construction, surface modification, and reaction environment regulation. Furthermore, an in-depth investigation of photocorrosion pathways and mechanisms is critical to accurately and effectively address the photocorrosion of semiconductor-based composites to improve PC/PEC water splitting performance in the future.

1. Introduction

Providing a steady stream of clean and renewable energy for society is a daunting task, especially in an era of increasing fossil energy consumption and carbon dioxide emissions.^{1–4} Overall water splitting based on photocatalytic (PC) or

photoelectrochemical (PEC) technology can convert or store solar energy in chemical bonds, which has attracted growing and intense interest since the landmark work of photocatalytic water splitting reported by Fujishima and Honda in 1972.^{5–7} Thermodynamically, overall water splitting should straddle the potentials of the hydrogen evolution reaction (−0.41 V vs. NHE)

Sha Chen received her B.S. from Jiangnan University in 2017. Currently, she is a PhD candidate under the supervision of Prof. Danlian Huang at the College of Environmental Science and Engineering, Hunan University, China. Her current research interests focus on the synthesis and application of functional photocatalysts.

Danlian Huang received her Ph.D. degree from Hunan University, China, in 2011. She is currently a professor at the College of Environmental Science and Engineering, Hunan University. Her research interests focus on the synthesis and application of functional microbes and functional materials in environmental remediation.

and oxygen evolution reaction (+0.82 V vs. NHE) (eqn (1)–(3)), which is an energetically uphill process.

In terms of practical application, high efficiency is a prerequisite for solar-chemical energy conversion, which depends on the following factors: (i) shortening the carrier transport distance to accelerate the transfer of excited photogenerated carriers to the catalyst surface;^{8,9} (ii) increasing the specific surface area to enhance the adsorption of water molecules;¹⁰ (iii) reducing the feature size over the critical size to facilitate charge carrier separation;^{11,12} (iv) increasing the band gap accompanying the conduction band (CB) or/and valence band (VB) edge shift to improve the thermodynamic driving force for surface reactions.¹³ Therefore, the band structure of the semiconductor for overall water splitting under light irradiation should satisfy the following conditions: (i) the band gap should be larger than 1.23 eV to straddle the oxygen evolution reaction potentials; (ii) the CB potential should be more negative than that for water reduction; (iii) the VB potential should be more positive than that for water oxidation.^{2,14} However, it is difficult to satisfy all the requirements with a single semiconductor photocatalyst; therefore, the existing research is dedicated to solving the above problems and has made breakthrough progress to obtain improved PC/PEC activity. Nevertheless, these improvements are sometimes limited by photostability issues, which results in an initial PC/PEC water splitting performance that decreases over time.

Up to now, TiO₂ has been the most widely investigated photocatalytic material for PC/PEC water splitting due to its excellent stability, affordability, and environmental friendliness. However, a severe limitation is that it can only be excited by ultraviolet light to show photocatalytic activity. Alternatively, various emerging semiconductors with excellent visible light response have been developed for PC/PEC water splitting, such

as WO₃, α -Fe₂O₃, BiVO₄, CdS, Cu₂O and so on.^{15–18} Of these, α -Fe₂O₃ can effectively absorb solar light with an energy distribution of 40% due to its narrow band gap of 2.1 eV, and its high solar-to-hydrogen (STH) efficiency of 16.8% and long-term stability (1000 h) render it a good candidate for PC/PEC water splitting. However, little success has been obtained on iron oxide due to its fast bulk recombination and short carrier diffusion length of no more than 10 nm.¹⁹ Although various strategies have been developed to improve the photocurrent density of α -Fe₂O₃, the obtained maximum photocurrent density is still far below its estimated theoretical value due to its inherent photoelectrochemical instability. Similar limitations also exist in other narrow band gap semiconductors, as displayed in Table 1.^{20–34} This photoelectrochemical corrosion refers to the photogenerated charge carriers participating in the self-oxidation and/or reduction of semiconductors rather than water splitting.^{35,36} As a typical example, metal sulfides are easily oxidized by photoexcited holes, causing the formation of sulfate (SO₄²⁻) in the presence of molecular oxygen and the formation of sulfur (S⁰) in the absence of molecular oxygen under light illumination, thereby resulting in a decrease in photocatalytic performance.³⁷ In view of the long-term photochemical stability of photocatalysts as a prerequisite for practical applications, research interests and efforts should be focused on how to overcome photocorrosion of semiconductor-based composites to achieve a long-term stable performance with respect to PC/PEC water splitting.

To date, the amount of research on the photocorrosion inhibition of semiconductors for PEC or/and PC water splitting has been increasing, and many feasible methods have been explored to enhance the photoreaction stability of PC/PEC water splitting systems, such as designing photocatalyst structures, constructing multicomponent composites, and optimizing reaction system conditions. In this regard, a comprehensive and timely overview regarding the latest developments and future directions of effective strategies toward photocorrosion inhibition of semiconductor-based composites in PC/PEC water splitting systems is highly desirable to promote the latest developments in this field of research, which have not yet been reported. Therefore, this review outlines recent advances in strategies to improve the photoreaction stability of PC/PEC water splitting systems, followed by discussing the tactics involved in improving the stability of PC/PEC water splitting systems with different photocorrosion mechanisms.

The review begins with the discussion of photocorrosion mechanisms of semiconductors under different circumstances. Taking typical semiconductors (CdS, ZnO and Cu₂O) as examples, the photocorrosion pathway in the presence of photo-generated electrons and/or holes is thoroughly clarified to provide a fundamental understanding of semiconductor instability under light irradiation. Then, a series of feasible characterization methods used to evaluate or confirm the stability of semiconductors are summarized. Most importantly, unlike most studies regarding water splitting aiming to achieve high efficiency by promoting the charge separation/transfer within the semiconductors, the focus of this review is on the recent

Table 1 Brief summary of some promising photocatalysts for PEC water splitting

Photocatalysts	Bandgap (E_g , eV)	Band edge positions V_{RHE} (V)	Theoretical photocurrent density STH efficiency	Best reported PEC performance	Ref.
CuO	1.7	VB at 2.16, CB at 0.46	35 mA cm ⁻²	3.7 mA cm ⁻² at 1.23 V_{RHE}	20
BiVO ₄	2.4	VB at 2.5, CB at 0.1	9.2%, 7.5 mA cm ⁻²	6.72 mA cm ⁻² at 1.23 V_{RHE}	21
Cu ₂ O	2.2	VB at 1.92, CB at -0.28	18.1%, -14.7 mA cm ⁻²	-10 mA cm ⁻² at 0 V_{RHE}	22
WO ₃	2.7	VB at 2.16, CB at 0.46	4.8%, 2.4 mA cm ⁻²	2.3 mA cm ⁻² at 1.23 V_{RHE}	23
TaON	2.5	VB at 2.1, CB at -0.4	7.8%, 6 mA cm ⁻²	4.57 mA cm ⁻² at 1.23 V_{RHE}	24
Ta ₃ N ₅	2.1	VB at 1.5, CB at -0.6	12.6 mA cm ⁻² , 15.9%	12.1 mA cm ⁻² at 1.23 V_{RHE}	25
CuWO ₄	2.2	VB at 2.6, CB at 0.4	13%, 10.7 mA cm ⁻²	1.5 mA cm ⁻² at 1.23 V_{RHE}	26
CaFe ₂ O ₄	1.9	VB at 1.3, CB at -0.6	21%, 17.5 mA cm ⁻²	1.2 mA cm ⁻² at -0.6 V Ag/AgCl	27
ZnFe ₂ O ₄	~2 eV	VB at 2.5, CB at 0.5	18%, 14.3 mA cm ⁻²	0.24 mA cm ⁻² at 1.23 V_{RHE}	28
CuBi ₂ O ₄	1.8 eV	VB at 1.17, CB at -0.63	24.1%, 19.7 mA cm ⁻²	2.5 mA cm ⁻² at 0.6 V_{RHE}	29
CuFeO ₂	1.5 eV	VB at 1.1, CB at -0.4	35%, 29 mA cm ⁻²	1.51 mA cm ⁻² at 0.35 V_{RHE}	30
LaTiO ₂ N	2.1 eV	VB at 1.9, CB at -0.2	15.8%, 12.5 mA cm ⁻²	6.5 mA cm ⁻² at 1.23 V_{RHE}	31
BaTaO ₂ N	1.8 eV	VB at 1.31, CB at -0.49	24%, 20 mA cm ⁻²	4.2 mA cm ⁻² at 1.2 V_{RHE}	32
CuInS ₂	1.53 eV	VB at 0.64, CB at -0.89	35%, 28 mA cm ⁻²	13.0 mA cm ⁻² at 0 V_{RHE}	33
CuGaSe ₂	1.7 eV	VB at 1.43, CB at -0.27	27.6%, 22.5 mA cm ⁻²	20 mA cm ⁻² at 0 V_{RHE}	34

advances in effective strategies for suppressing photocorrosion of semiconductor-based composites with respect to their intrinsic properties and interface charge transfer kinetics, including morphology/size control, heteroatom doping, heterojunction construction, surface modification, and reaction environment regulation. Finally, the daunting tasks that future research efforts should be focused on are discussed, aiming to accurately and effectively solve the photocorrosion of semiconductors to further improve the PC/PEC water splitting activity and realize the long-term performance of PC/PEC water splitting in practical applications.

2. Understanding the photocorrosion mechanism toward PC/PEC water splitting

A precondition for introducing PC/PEC water splitting into practical applications is to improve the stability of semiconductor materials without sacrificing catalytic activity. However, many semiconductors suffer from severe photocorrosion under light irradiation, which results in a gradual

decrease in activity as irradiation time increases.³⁸ An in-depth investigation of the mechanism of semiconductor photocorrosion is conducive to the development of a series of feasible strategies to improve the photoreaction stability of semiconductors. In general, whether semiconductors undergo photochemical corrosion depends on the alignment of the reduction potential (ϕ_{re}) relative to the conduction band minimum (CBM) or the oxidation potential (ϕ_{ox}) relative to the valence band maximum (VBM). As shown in Fig. 1, a semiconductor with a VBM lower than ϕ_{ox} (O_2/H_2O) will suffer from oxidation by unconsumed holes, such as CdS, ZnO, ZnS, TiO₂ and so on. Similarly, a semiconductor with a CBM higher than ϕ_{re} (H^+/H_2) will suffer from reduction by unconsumed electrons, such as Cu₂O, BiVO₄, WO₃ and so on.³⁹ In this section, the photocorrosion pathway in the presence of photogenerated electrons and/or holes is thoroughly discussed with three typical semiconductors (CdS, ZnO and Cu₂O) as examples, which can also be compared to other semiconductors.

Sulfide semiconductors are regarded as promising candidates for photocatalytic hydrogen evolution due to their strong visible light absorption capacity and

Fig. 1 The relationship between band edge position and self-reduced and/or oxidized potential for various semiconductors. Reprinted with permission from ref. 39. Copyright 2012, American Chemical Society.

thermodynamically favorable band structure.⁴⁰ However, photogenerated hole-induced instability leads to a decrease in photocatalytic performance as the irradiation time increases, which greatly limits the application of sulfide semiconductors in photocatalytic hydrogen evolution.⁴¹ Taking CdS as an example, under light irradiation, CdS is excited to produce photo-generated electron-hole pairs after absorbing more energy than its band gap. The surface sulfur ions of CdS would be oxidized to S⁰ in the absence of oxygen ($\text{CdS} + 2\text{h}^+ \rightarrow \text{Cd}^{2+} + \text{S}$)⁴² and to SO₄²⁻ in the presence of oxygen ($\text{CdS} + 4\text{h}^+ + \text{H}_2\text{O} + \text{O}_2 \rightarrow \text{Cd}^{2+} + \text{SO}_4^{2-} + 4\text{H}^+$)⁴³ if the VB-holes of CdS cannot be consumed or withdrawn in a timely manner, thereby resulting in CdS inactivation.

Similar hole-induced photocorrosion also exists in PEC systems; taking ZnO as an example, the lattice oxygen of ZnO, rather than the oxygen atoms in water molecules, is oxidized by photogenerated holes to release zinc ions ($2\text{ZnO} + 4\text{h}^+ \rightarrow 2\text{Zn}^{2+} + \text{O}_2$), thereby resulting in the dissolution of the ZnO photo-electrode. Generally, the photo-induced dissolution of ZnO involves the following steps. The excited holes are first transferred from the VB to the catalyst surface ($\text{O}_{\text{surface}}^{2-} + \text{h}^+ \rightarrow \text{O}_{\text{surface}}^-$ and $\text{O}_{\text{surface}}^- + 3\text{O}^{2-} + 3\text{h}^+ \rightarrow 2(\text{O} - \text{O}^{2-})$), followed by the oxidation of the lattice oxygen ($(\text{O} - \text{O}^{2-}) + 2\text{h}^+ \rightarrow \text{O}_2$) accompanied by the dissolution of Zn²⁺ ($2\text{Zn}^{2+} \rightarrow 2\text{Zn}^{2+}$).⁴⁴

Unlike CdS and ZnO semiconductors, Cu₂O, a semiconductor widely used for photocatalytic hydrogen evolution, has a more complex photocorrosion pathway, involving hole-induced oxidation of Cu₂O ($\text{Cu}_2\text{O} + 2\text{OH}^- + 2\text{h}^+ \rightarrow 2\text{CuO} + \text{H}_2\text{O}$) and electron-induced reduction of Cu₂O ($\text{Cu}_2\text{O} + \text{H}_2\text{O} + 2\text{e}^- \rightarrow 2\text{Cu} + 2\text{OH}^-$).^{45,46} More importantly, the redox potential of Cu₂O is between its CB and VB potential, which causes one or both of the electron and/or hole driven photocorrosion to occur.⁴⁷ Notably, the effects of environmental media such as O₂ and pH on the stability of semiconductors under light irradiation also should be taken into consideration. For instance, whether the photocorrosion product of CdS is SO₄²⁻ or S⁰ depends on the presence or absence of oxygen molecules. Besides, CdS suffers from serious photooxidative dissolution under acidic conditions even without light irradiation, while photocorrosion and leaching can be effectively inhibited in a high pH solution.

Based on the above discussion, a decrease in photostability would have a significant adverse effect on PC and/or PEC water splitting performances. Therefore, it is necessary to control the undesired reaction between excited holes or/and electrons and the semiconductor, while promoting the separation and migration of electron-hole pairs to accelerate the photocatalytic redox reaction, thereby resulting in improved PC/PEC water splitting activity and stability. To this end, tremendous strategies have been developed to improve the photoreaction stability of PC/PEC water splitting systems such as morphology/size control, reaction environment regulation, heterojunction construction and so on, which will be discussed in the subsequent section. Notably, a comprehensive understanding of the characterization methods used to evaluate semiconductor stability is essential and will be the focus of the next section.

3. Advanced characterization methods of semiconductor-based catalysts for PC/PEC water splitting

The stability of the photocatalyst is an important indicator to determine whether it can be reused in practical applications, which is usually evaluated by successive cycle tests. That is, the used catalyst is collected and reused for several cycles under the same experimental conditions as the fresh sample.⁴⁸⁻⁵¹ However, it is not convincing to use the catalyst cycle performance as an indicator to evaluate the photostability of the catalyst, as other factors may also result in a decrease in photocatalytic performance after multiple recycle tests, such as active site blocking, loss of sample during recycling, adsorption of intermediates, or surface changes. Therefore, it is necessary to characterize the surface morphology/structure of the sample after multiple cycles to further determine the stability of the photocatalyst.

In general, electron microscopy such as scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD), and X-ray photoelectron spectroscopy (XPS) is applied to analyze the morphological information, crystal structure, and surface properties of the reused catalysts to investigate the structural changes of the photocatalysts before and after the reaction, thereby evaluating the photostability of the sample.⁵² For instance, Chen *et al.* reported that the prepared MoS₂/CdS catalyst showed a long-term stability toward photocatalytic water splitting, and the hydrogen production was almost the same every 5 h (Fig. 2a).⁵³ The excellent stability can be confirmed by SEM (Fig. 2b) and XRD (Fig. 2c) characterization, in which no significant difference in the XRD pattern and surface morphology was observed between the used and fresh catalysts, suggesting that the photocorrosion of CdS caused by holes can be effectively inhibited. In another example, Zhou *et al.* found that the photostability of CdS nanorods was greatly improved after being modified with amorphous turbostratic carbon nitride layers (CN_x) (Fig. 2d and e).⁵⁴ Comparing the TEM images of the used sample, no obvious etching was found for the used CdS-Pt/CN_x and CdS/CN_x-Pt, while severe photocorrosion was detected in the used CdS-Pt sample, indicating that the modification with the CN_x layer can effectively inhibit the instability of CdS under light irradiation (Fig. 2f and g).

The photocorrosion of metal sulfide-based composite catalysts is caused by the hole-induced oxidation of surface lattice S²⁻ to S⁰ and/or SO₄²⁻, which results in a change in the surface structures of the metal sulfide in the composite.⁴¹ Therefore, investigating the valence state of the element S in the metal sulfide composite before and after multiple cycle reactions is conclusive evidence for evaluating the photoreaction stability of the composite, which can be achieved by XPS characterization. For instance, ternary ZnO-CdS-MoS₂ (ZCM) exhibited an improved photocatalytic performance and stability for hydron evolution after light tuning from visible light to UV-vis light, which was attributed to interfacial charge transfer following a traditional type-II heterojunction under visible light while a Z-

scheme under UV-vis light (Fig. 3a).⁵⁵ As proven from the XPS spectra of the fresh and used sample, only little S^0 generated by oxidation of the surface lattice S^{2-} by excited holes can be found in the used sample (Fig. 3b); the Cd 3d spectra displayed in Fig. 3c showed that no obvious decrease in intensity could be found under UV-vis irradiation while a significant decrease occurred under visible light irradiation, suggesting higher photocatalytic stability under UV-vis light.

In addition to characterizing the changes in morphology, structure, and element valence state of the catalyst before and after the reaction, the use of inductively coupled plasma optical emission spectroscopy (ICP) to determine the concentration and type of ions in the solution after the reaction to evaluate whether the catalyst is dissolved during the photoreaction is also strong evidence to prove the stability of the catalyst.^{56–58} For instance, since CdS deactivation is caused by the oxidation of S^{2-} by photogenerated holes, monitoring the leakage content of Cd^{2+} in the reaction process can effectively evaluate the photoreaction stability of CdS-based photocatalysts.^{59,60} As reported by Xie and co-workers, no detectable Cd^{2+} leaching was observed after ten cycles in the presence of ZnO-CdS-MoS_2 catalysts under UV-vis

irradiation, while there was 0.0434 mg L^{-1} leakage of Cd^{2+} after visible light irradiation (Fig. 3d), suggesting that the photocorrosion resistance of CdS was greatly enhanced with UV-vis irradiation.⁵⁵ This difference in stability resulting from the irradiation light source was attributed to the charge transfer following the Z-scheme mechanism under UV-vis irradiation while the type-II charge transfer pathway in the case of visible light irradiation: the former reduced the accumulation of VB holes in CdS, thereby effectively preventing CdS from being oxidized by photogenerated holes.

Although the above characterization techniques can demonstrate photocorrosion of semiconductors to some extent, there is always some photoreaction instability that cannot be demonstrated by conventional characterization due to the uncertainty of the photocatalytic reaction process. For instance, Ma *et al.* investigated the microstructural changes of CdS before and after the photocatalytic hydrogen evolution reaction with $\text{Na}_2\text{S-Na}_2\text{SO}_3$ as the electron donor through various techniques.⁶¹ No obvious difference was detected between fresh and used CdS by conventional structural characterization such as XRD (Fig. 3e), SEM (Fig. 3f) and XPS (Fig. 3g). However,

Fig. 3 (a) Cycling test of photocatalytic H₂ evolution for ZCM under visible light and UV-vis irradiation for 20 h; (b) comparison of S 2p XPS spectra of fresh and used ZCM; (c) XPS survey spectra of Cd 3d for ZCM before and after ten cycles. photocatalytic hydrogen production under argon was much higher than that under air, which indicated that partial photocorrosion of CdS occurred during photocatalytic hydrogen evolution in air, while this change cannot be proven by conventional structural characterization. Since optical phonons can significantly affect the carrier relaxation process and emission efficiency in semiconductor nanostructures, which can be probed by Raman spectroscopy, they further designed a simple photocatalytic system equipped with *in situ* Raman analysis to monitor the microscopic changes in CdS during the photocatalytic reaction, revealing the relationship between the interfacial crystal lattice and photocorrosion at the spectral level. It was observed that the peak intensity at 500 cm⁻¹ belonging to CdO increased as the reaction proceeded, and the peak intensity at 500 cm⁻¹ was significantly lower under argon than in air during the first 100 min of the reaction, both of which indicated that the surface S atoms were replaced by O (Fig. 4a and b). The increase in lattice stress during the photo-reaction in air was attributed to a physically and/or chemically enhanced interaction between absorbed O₂ and the

photocatalyst surface, which in turn resulted in a lower photocatalytic performance.

For the PEC system, the use of narrow bandgap semiconductors, especially quantum dots (QDs) (PbS,⁶² CdS,^{63,64} and CdSe QDs^{65,66}) to sensitize photoelectrodes has been widely developed in PEC hydrogen evolution reactions due to the wider light absorption range from UV to visible light and adjustable band gap energy of QDs. Similar to photocatalytic systems, currently developed QDs for sensitized photoelectrodes still have significant limitations, owing to poor photostability and long-term durability. However, considerable studies have proven that the instability of QDs is caused by the anodic photocorrosion since the rate of interfacial hole injection in the electrolyte is slower than the rate at which electrons are transferred to the metal oxide. However, a technique for direct and quantitative analysis of photocorrosion of QDs is still needed. At present, an *in situ* analysis method is developed to investigate the photocorrosion mechanism of QDs and propose a possible solution to photocorrosion. In a typical example, Choi *et al.* prepared CdSe/CdS/ZnO nanowire arrays as PEC photoanodes using a quartz crystal microbalance (QCM) as a platform, with

simultaneous mass analysis.⁶⁷ The SEM image showed that the structure of the CdSe/CdS/ZnO photoanode was destroyed after the water splitting reaction, which was due to the anodic photocorrosion of QDs (Fig. 4c and d). The current density–time curve showed that the photocurrent density of CdSe/CdS/ZnO and CdS/ZnO photoanodes decreased sharply with PEC water decomposition until it was consistent with the photocurrent level of the pure ZnO anode (Fig. 4e), which was attributed to anode oxidation caused by photogenerated holes. The photogenerated electrons of QDs can be effectively migrated to ZnO and transfer to counter electrons by electrical connection, while the holes cannot be consumed in a timely manner since the oxygen evolution reaction involving four electrons is more difficult, thereby resulting in accumulated photogenerated holes participating in the anodic corrosion reaction (Fig. 4f). The anodic corrosion in turn caused the decrease in the mass of the quartz crystal microbalance, which can be reflected by the highest resonance frequency variation of CdSe/CdS/ZnO compared to ZnO and CdS/ZnO (Fig. 4g).

Generally, traditional characterization can determine whether the catalyst suffers from photocorrosion during photocatalysis from the changes in morphology, crystal structure,

elemental valence of the catalyst before and after the reaction, and composition of the solution after the reaction. However, considering the complexity and uncertainty of the reaction process, further research should focus on the development of *in situ* monitoring techniques to investigate changes in the morphology and structure of semiconductors in the photoreaction process, which provides more convincing evidence for assessing the photoreaction stability of materials.

4. Strategies to improve the stability of semiconductor-based composites for PC/PEC water splitting

In order to obtain a PC/PEC water splitting system with high activity and long-term stability for practical application, one of the difficulties is how to overcome the photocorrosion of the semiconductor under light irradiation. To date, a considerable number of strategies for this topic have been developed to obtain long-term stable and efficient catalysts. Therefore, the focus of this section is on systematically elaborating various strategies developed to improve the stability of semiconductor

composites, such as optimizing the physical/chemical properties of the semiconductor, foreign atom doping, constructing heterojunctions, loading with cocatalysts, and adjusting reaction conditions.

4.1. Crystal structure, morphology and size control

Due to the structure-determining function, optimizing the physical properties of the semiconductor can result in an improved stability under light irradiation.⁶⁸ In most cases, increasing the crystallinity of the semiconductor is beneficial to enhance the photocatalytic activity and stability because the increase in crystallinity can promote the charge transfer and reduce the number of recombination centers of photogenerated electrons and holes. In addition, the morphology and size of the semiconductor depend on its physical and/or chemical properties,^{69,70} which in turn determines the photocatalytic activity and stability of the catalyst. Accordingly, considerable research studies have focused on designing materials with the desired structural morphology to prevent photo-induced instability in various photocatalytic applications.

4.1.1. Crystallinity-dependent functions. In view of the increase in the crystallinity of the semiconductor, the number of recombination centers of photogenerated electron-hole pairs can be reduced, thereby improving the photocatalytic performance and stability. For example, Jing used a highly crystallized CdO precursor treated by thermolysis as a hard template to prepare CdS in the presence of H₂S (CdS-S-*m*, *m* is the temperature of thermal treatment).⁷¹ For comparison, CdS samples prepared by one step precipitation or by two step precipitation-thermal treatment under a N₂ atmosphere, denoted as CdS-C-*m*, were also synthesized. Since hexagonal Pt/CdS-S-400 with high crystallinity has less surface oxygen atoms, the separation efficiency of photogenerated electrons and holes can be greatly enhanced. As a result, the hydrogen production of Pt/CdS-S-400 was maintained at a high level even after five cycles as compared with other samples (Fig. 5a and b). Moreover, increasing the crystallinity of CdS is also an effective method to obtain a long-term durability for PEC photoanode application. As reported by Cao *et al.*, the current density of CdS/ZnO nanorod arrays was improved after being annealed under an argon atmosphere at 600 °C due to the improved crystallinity of the CdS film.⁷² After being decorated with ZnFe₂O₄, the current density of CdS/ZnO/ZnFe₂O₄ was stable at a high level for a long time (Fig. 5c), which was due to the fact that the improved crystallinity of CdS lowered the resistance of charge transfer, while the holes of CdS could be effectively transferred to ZnFe₂O₄, thereby preventing CdS from being oxidized by its VB holes (Fig. 5d).

However, excellent crystallinity is not always beneficial for improving photocatalytic performance and stability. In a typical example, Fang *et al.* proposed that dual-defective construction in which defective few-layered MoS₂ was grown *in situ* on defective layered In₂S₃ could also obtain remarkable performance and impressive photostability.⁷³ The existing abundant disordered crystal structures broke the strict crystal anisotropy of In₂S₃ and formed homogenous bond situations in all

orientations. Therefore, the vast majority of In₂S₃ molecules remained at similar energy levels, with the exception of those relatively unstable positions occupied by the MoS₂ cocatalyst. Under illumination, the photo-excitons generated in the crystallite region extend throughout the In₂S₃ layer. When concentrated in intimate binding sites, photogenerated electrons expediently flew through the interface channel to defective MoS₂ layers that possessed less negative CB potential than In₂S₃ and readily reduced H⁺ to H₂, while the holes cannot easily find energy-unbalanced bonds to attack to cause photocorrosion due to the isotropy of the disordered structures. In contrast, the holes continued to travel in In₂S₃ until being consumed by the sacrificial reagents to induce oxidized products (Fig. 5e). Therefore, a remarkable performance and impressive photostability for photocatalytic hydrogen production can be obtained through such dual-defective construction (Fig. 5f).

4.1.2. Size-dependent functions. It is widely accepted that reducing the particle size allows the semiconductor to expose more active surface sites to participate in the photoreaction, thereby improving photocatalytic performance. In fact, the particle size also affects the photogenerated charge transfer efficiency, which in turn determines the stability of the semiconductor depending on the charge transfer.^{74,75} Therefore, efforts and interest have been focused on designing semiconductor-based composites with controllable size to obtain efficient and stable photocatalytic performance. For instance, Singh and co-worker reported that oxygen vacancy-enriched Cu₂O nanoparticles (NPs) prepared by hydrolysis of a sCu(i)-triethylamine (Cu(i)-TEA) complex exhibited more excellent photostability than commercial Cu₂O, with only 20% loss of photocatalytic activity after 10 cycles. This enhanced stability was attributed to the fact that the as-prepared Cu₂O with a six times smaller size than commercial Cu₂O can provide more active sites for the photocatalytic reaction, thereby effectively inhibiting Cu₂O self-oxidation and/or reduction caused by photogenerated carriers.⁷⁶ In the case of PEC, Shahbazi and Kiani reported that Cu₂O porous foam with nanostructure walls exhibited a high photocurrent stability for 7200 s compared to the Cu₂O sheet. This enhanced stability was due to the fact that the porous structure of Cu₂O foam facilitates electron transfer to the reaction sites.⁷⁷

Besides, in view of the non-directionality in the semiconductor growth process, it is difficult to accurately control the size of a semiconductor simply by optimizing the reaction parameters in the synthesis process. Therefore, the use of the structural characteristics of the host material to orientate the target semiconductor is a feasible strategy to achieve size controllability, with mesoporous materials being the preferred host material.⁷⁸⁻⁸⁰ Taking CdS clusters as an example, theoretically, confining CdS clusters in a porous support can enhance its photostability by reducing the exposed area of CdS and control the size of CdS due to quantum confinement which resulted in a negative shift of the CB edge. As a result, semiconductors with small dimensions allow charge carriers to diffuse rapidly to surface active sites, thereby minimizing the bulk recombination of electron-hole pairs in CdS clusters. In addition, the host porous material provides additional electron

transfer channels to promote the separation of charge carriers and further improve the photocatalytic performance. In this regard, Peng *et al.* prepared CdS incorporated Ti-MCM-48 mesoporous materials for overall water splitting with ethanol as sacrificial electron donor under 300 W Xe lamp irradiation. XPS analysis showed that no obvious difference in the intensity of Cd and S was detected between fresh and used catalysts,

suggesting that the stability of CdS was effectively enhanced after encapsulation in the MCM-48 matrix, thereby achieving high water splitting efficiency after three cycles.⁸¹

4.1.3. Morphology-dependent functions. Moreover, optimizing the structure and morphology of the semiconductor has been demonstrated to be a feasible strategy to improve the photocorrosion resistance of the catalyst since the surface atom

coordination and surface electronic structure of different morphology are different.^{82–84} As confirmed by Zheng *et al.*, extending the (111) facet exposure ratio of Cu₂O can greatly improve the photocatalytic stability due to the (111) facet having the lowest surface free energy.⁸⁵ A similar conclusion was also reported by Kwon *et al.*: relatively slight surface photocorrosion was detected in octahedral Cu₂O with less (111) facet exposure, while relatively significant surface photocorrosion occurred in rhombic dodecahedral Cu₂O with more (111) facet exposure under 300 W Xe lamp irradiation for 9 h (Fig. 5g).⁸⁶ Cu 2p XPS analysis showed that the rhombic dodecahedral Cu₂O had the largest peak area ratio of Cu(II) to Cu(I), followed by cubic Cu₂O, and the smallest ratio was present in octahedral Cu₂O, indicating that higher photostability existed in rhombic dodecahedral Cu₂O (Fig. 5h). In addition, Bhavani and his co-worker prepared urchin-type CdS nanorods with a Mo-doped W₁₈O₄₉ cocatalyst integrated.⁸⁷ The urchin-type morphology greatly shortened charge carrier transfer distance, and the oxygen deficiency and Mo dopant could increase the number of active sites. As a result, only a slight decrease in hydrogen evolution was found after four cycles, suggesting good resilience to photocorrosion.

In the case of PEC systems, coating the photoelectrode with a protective overlayer to avoid direct contact of the electrode with the electrolyte is a viable strategy to obtain enhanced stability. The thickness of the protective overlayer depends on the carrier transport lifetime, and the thickness of currently reported photoanode is typically less than 200 nm in order to compensate for the short carrier diffusion length. However, thin protective overlayers usually have high transparency, which allows most of the visible light to pass through, resulting in poor light absorption. In order to improve the light absorption efficiency, depositing a thick protective overlayer on the photoanode by engineered architectures might be a feasible strategy. In a typical example, Qiu *et al.* constructed an engineered cone-shaped nanostructure to achieve the deposition of an approximately 700 nm-thick nanoporous Mo-doped BiVO₄ layer, which effectively overcame the barrier of incompatibility between light absorption capability and carrier transfer distance (Fig. 5i).⁸⁸ The total thickness of the BiVO₄ film was increased after constructing the nanocone arrays due to the shortened charge transfer distance which allowed for efficient collection of charge around the conductive nanocones. Moreover, the unique structure allowed light to be scattered multiple times inside to increase the optical path, thereby further improving the light absorption capacity. This cone-shaped nanostructure resulted in an excellent stability, which could be demonstrated by the stable perovskite solar cell after 10 h and unchanged morphology between the fresh and used sample (Fig. 5j). Moreover, embedded/hierarchical catalysts with a sandwich structure have recently been developed to prevent electrode photocorrosion. For example, Li *et al.* reported that the stability of Si nanowires could be greatly improved after successively depositing Pt NPs and a TiO₂ passivated layer to construct a sandwich structure.⁸⁹ A more complex sandwich structure was also employed by Yang *et al.* to improve the stability of black Si (bSi) photoelectrodes, that is, a 20 nm-thick

TiO₂ layer and Pt NPs were deposited on top of nano-porous Si, followed by the deposition of a 2 nm-thin second TiO₂ layer. The prepared photoelectrodes with such a dual-TiO₂-layer sandwich structure exhibited more excellent stability than a single (TiO₂/Pt/bSi, Pt/TiO₂/bSi) or non-protective layer (Pt/bSi).⁹⁰ Other photoelectrodes with a similar sandwich structure were also reported by the Chidsey group.⁹¹ Furthermore, Gu and co-worker designed a GaInP₂ photocathode with a graded catalytic-protective layer by annealing an amorphous-MoS_x/TiO_x-GaInP₂ stack at 450 °C.⁹² Annealing treatment resulted in a large degree of mutual penetration between MoS_x, TiO₂ and GaInP₂, while there was a relatively clear boundary between the components before annealing. As a result, the annealed MoS_x/TiO_x-GaInP₂ photocathode showed an enhanced stability compared to the sample without annealing.

4.2. Doping effects

Heteroatom doping is regarded as an efficient strategy to enhance the performance and stability of semiconductors since the doping of foreign elements can alter the band gap of the semiconductor by introducing an impurity level in the forbidden band or forming a solid solution, which extends its light absorption range and promoted the separation efficiency of electron-hole pairs, thereby reducing the possibility of photocorrosion caused by excited electrons or/and holes.

4.2.1. Cation doping. The substitution of cations in the crystal lattice of a semiconductor can form impurity energy levels within the band gap. As reported by Lee *et al.*, Cu-doped ZnS microspheres exhibited long-term stability for photocatalytic hydrogen evolution for up to 48 h light irradiation.⁹³ There was no significant difference in the XRD patterns of the samples before and after the reaction, indicating that Cu doping could greatly improve the photocorrosion resistance of ZnS. This enhanced photostability was attributed to the fact that Cu²⁺ doping into the lattice or interstitial sites of ZnS could generate trap energy levels near the CB of ZnS, which could accept the excited electrons from the VB of ZnS, resulting in an enhanced charge separation efficiency, which in turn improved the stability of single ZnS (Fig. 6a).

For PEC systems, it has been demonstrated that coating a protective layer on the surface of the photocathode can improve its durability, while it is also limited by a duration of less than one hour. Masudy-Panah reported that long-term stability was achieved in Al-incorporated CuO photocathodes because the photogenerated electrons of CuO could be effectively transferred from the photocathode to the electrolyte, thereby preventing CuO from being reduced by photogenerated electrons.²⁰ The XPS spectra (Fig. 6b) and the XRD peaks (Fig. 6c) of the photocathodes after the stability test showed that the peak of CuO at binding energies of 932.7 and 952.8 eV and the Cu₂O XRD peak intensity at a 2θ of 36.45° of the CuO:Al photocathode were much lower than those of the CuO photocathode, suggesting that the incorporation of Al into CuO curbed the reduction of CuO and resulted in improved photoreaction stability. The SEM image of the CuO and CuO:Al

photocathodes after the stability test shows the same conclusion (Fig. 6d).

4.2.2. Anion doping. The anionic substitution of an inorganic semiconductor will result in a change in its electronic structure and light absorbing ability, thereby affecting its photoreaction stability. Theoretically, Kouser and co-workers evaluated the effects of co-substitution of P and Cl on the photocatalytic hydrogen evolution of CdS and ZnS through density functional theory (DFT) calculations.⁹⁴ An isolated sub-band near the VB was formed after P substitution since P atoms preferentially occupied Cd sites, which resulted in a decrease in the band gap of CdS. Experimentally, Huang *et al.* reported that CdS with gradient P-doping could achieve excellent photocatalytic performance and stability for hydrogen evolution (Fig. 6e).⁹⁵ Since P doping increased the Fermi level (E_f), E_f equilibrates and band bends occurred under light irradiation, leading to the formation of an n-n⁺ homojunction, which facilitated photogenerated charge transfer from the inside to the surface sites driven by the built-in electric field (Fig. 6f and

g). In addition, since the S sites were “hidden” inside, the hole-induced photocorrosion was effectively inhibited (Fig. 6h). As a result, CdS with P atom doping exhibited an excellent photocatalytic performance for hydrogen evolution, and no obvious decrease in hydrogen production was detected even after six cycles.

Moreover, since the photocorrosion of ZnS results from the oxidation of lattice S²⁻ by excited holes, lowering the oxidizing ability of VB holes is a thermodynamically feasible method to improve the photocorrosion resistance of ZnS. In addition, the energy of the N 2p orbital is higher than that of the O 2p orbital; substituting S with N sites of metal sulfides can reduce the band gap by increasing the VB potential, thereby lowering the oxidizing capability of holes. In this regard, Zhou *et al.* prepared N-doped ZnS by nitriding ZnS powder in an NH₃ atmosphere.⁹⁶ DFT calculations revealed the VBM of ZnS was increased after nitrogen heteroatoms occupied the S sites, but the CBM still basically consisted of the Zn 4s states and small S 3p states with a small position change. That is, the CB electrons still

maintained high reduction ability while the oxidative capacity of holes was weakened, which effectively inhibited the hole-induced photocorrosion of ZnS, resulting in less dissociation in aqueous solution for the N-doped ZnS sample. As a result, N-doped ZnS showed excellent stability for photocatalytic hydrogen evolution under simulated sunlight irradiation for 12 h.

4.2.3. Formation of a solid solution. Compared to the corresponding matrix materials with defined wide or narrow bandgap semiconductors, solid-solution photocatalysts usually exhibit controllable bandgap and band edge positions by forming new orbital hybrids, which facilitate the improvement of photocorrosion resistance of semiconductor-based catalysts. For instance, a multicomponent sulfide solid solution, $\text{Cd}_{0.1}\text{Sn}_x\text{Zn}_{0.9-2x}\text{S}$, was prepared through a hydrothermal process, which had a higher hydrogen production and was more stable under visible light irradiation compared with $\text{Cd}_{0.1}\text{Zn}_{0.9}\text{S}$ solid solution.⁹⁷ Cycling experiments showed that an obvious decrease in hydrogen production was detected in the presence of $\text{Cd}_{0.1}\text{Zn}_{0.9}\text{S}$ in the second cycle, while almost the same hydrogen production was observed to that obtained in the first cycle for $\text{Cd}_{0.1}\text{Sn}_x\text{Zn}_{0.9-2x}\text{S}$. This improved photocatalytic stability was due to the addition of Sn resulting in a larger energy difference between CB and VB, endowing the excited electrons and holes with enhanced separation efficiency and longer lifetime, thereby greatly improving the photocatalytic performance and stability. In another example, Zhang *et al.* reported that Cu ion doping greatly improved the photocatalytic stability of $\text{Zn}_x\text{Cd}_{1-x}\text{S}$.⁹⁸ The prepared $(\text{Zn}_{0.95}\text{Cu}_{0.05})_{1-x}\text{Cd}_x\text{S}$ solid solution exhibited an improved photocatalytic performance for hydrogen evolution using $\text{Na}_2\text{SO}_3\text{--Na}_2\text{S}$ as the sacrificial agent, and the stability experiments showed that just a slight decrease in hydrogen evolution was found after three cycles (12 h), owing to the consumption of the sacrificial reagents, indicating relatively good long-term stability. In PEC systems, Stein *et al.* used combinatorial wedge-type multilayer deposition to prepare two photocathodes, Si-doped Cu_3TiO_x ($\text{Si}:\text{Cu}_{75}\text{Ti}_{25}\text{O}_x$) and Ti-doped CuSiO_3 ($\text{Ti}:\text{Cu}_{50}\text{Si}_{50}\text{O}_x$), which exhibited relatively higher and more stable photocatalytic hydrogen evolution performance.⁹⁹ Linear sweep voltammogram results demonstrated that the stability was enhanced by decreasing the Cu content or increasing the Ti/Si constant. Comparing both quasi-binary material compositions, the introduction of Si resulted in more stable films than the introduction of Ti.

4.3. Hybridization with cocatalysts

It is generally believed that the cocatalyst can act as a reaction site and catalyze the surface redox reaction, promoting charge separation and transfer driven by the interface generated between the cocatalyst and semiconductor. Loading suitable cocatalysts with a larger work function for electron sinks or lowering the overpotential for hole transfer on the semiconductor can effectively alleviate the photocorrosion of the composites, which is due to the fact that the photogenerated charge carriers and accumulated active sites can be consumed in a timely manner or transferred.^{99–103} In this section, how the

cocatalyst enhances the stability of semiconductor photocatalysts in various photocatalytic reactions will be systematically discussed.

4.3.1. Metal cocatalysts. Numerous studies have confirmed that loading a metal cocatalyst can improve the photocatalytic performance and, more importantly, greatly alleviate the photocorrosion of semiconductors by accelerating charge transfer of semiconductors.^{104–109} For instance, recent work has demonstrated that Cr/MoS₂ with metal Cr on the MoS₂ nano-sheet surface exhibited enhanced photocatalytic activity and stability during photocatalytic hydrogen evolution compared to single MoS₂.¹¹⁰ After loading the metal NPs, a well-defined interface formed between the metal and MoS₂ acted as an electron trap to capture photogenerated electrons and significantly suppressed bulk recombination of photogenerated charge carriers in MoS₂, thereby resulting in a long-term stable performance for hydrogen evolution. In fact, due to the lower Fermi energy of noble metals, it is considered to be the most common cocatalyst for promoting the separation of electrons and holes, which in turn results in an improved photocatalytic performance and stability.^{111,112} Yuan *et al.* reported that the introduction of gold nanoparticles (Au NPs) greatly improved the structural stability of Cu₂O.¹¹³ In another example, Liu and co-workers demonstrated that CdS/(Au-ReS₂) nanospheres exhibited highly efficient and stable performance for photocatalytic hydrogen evolution under 300 W xenon lamp irradiation using $\text{Na}_2\text{SO}_3\text{--Na}_2\text{S}$ as sacrificial reagent.¹¹⁴ Stability experiments showed that CdS/(Au-ReS₂) retained 133% of its initial hydrogen production after five consecutive photocatalytic reactions even without the addition of new sacrificial agents. This excellent stability was attributed to the enhancement of the local field resulting from the combination of magnetic and electric dipole resonance around the Au NPs on the surface of ReS₂ NPs, which accelerated the electron transfer from CdS to ReS₂. In addition, due to the intimate contact of Au and ReS₂, the transfer of the plasmon-induced hot electrons on Au NPs to ReS₂ was also beneficial to the photoexcited charge separation in CdS. Thanks to the above merits, CdS/(Au-ReS₂) showed excellent persistence and reusability towards photocatalytic hydrogen evolution under light irradiation.

However, metal cocatalyst loading also has some disadvantages, that is, the metal NPs are generally deposited on the surface of the semiconductor, which causes the metal NPs to be directly exposed to the surrounding reaction environment, resulting in the possibility of metal dissolution during the reaction. As a result, metal NPs may be dissolved during the reaction, resulting in a decrease in photocatalytic performance and stability.^{115,116} In addition, the metal cocatalysts are detached from the semiconductor domains and are severely aggregated due to the oxidation of the interface by photogenerated holes in the reaction process. In order to overcome the above problems, Choi proposed an effective physical separation between the reduction and oxidation sites by constructing a double shell structure (Fig. 7a).¹¹⁷ The reaction activity of Pt-CdS double shell hollow nanocubes remained at its initial value for up to 20 h without deactivation (Fig. 7b), while the original morphology of the hollow nanocubes was retained

Fig. 7 (a) General synthetic approach of M–CdS double shell hollow nanocubes ($M = \frac{1}{2}\text{Pt}$, Au, and Pd) and SEM and TEM images of Pt–CdS and Pt–CdS hollow nanocubes; (b) time course of H_2 generation using Pt–CdS double shell hollow nanocubes (black) and commercial CdS platinized by photo-deposition (red); (c) TEM image of Pt–CdS hollow nanocubes after 10 cycles of H_2 generation. Reprinted with permission from ref. 116. Copyright 2016, Royal Society of Chemistry. Copyright 2015, American Chemical Society.

(Fig. 7c). In contrast, the performance of Pt–CdS spheres, in which Pt was photo-deposited on commercial CdS spheres, dropped by 50% over 20 h (Fig. 7b), which was due to the detachment and aggregation of Pt from the CdS surface. The improved stability of the Pt–CdS hollow nanocubes indicated that such a double shell structure could effectively consume photogenerated holes from the sacrificial reagents through the external CdS surface. The concept of physical separation was also reported by Jiang *et al.*, where the activity and stability of $\text{Cu}_2\text{ZnSnSe}_4$ regarding PEC water splitting were greatly improved after coating with an In_2S_3 /CdS double layer and the deposition of Pt particles.¹¹⁸ The surface coating of the In_2S_3 layer acted as a mediator for efficient electron transfer to Pt deposits and a protecting layer to avoid contact between the CdS layer and outer electrolyte solution, resulting in excellent durability. As shown in Fig. 7d–g, an obvious dissolution was detected for Pt/CdS/ $\text{Cu}_2\text{ZnSnSe}_4$ after the durability test, while the morphology and structure were well maintained before and after reaction in the case of Pt/ In_2S_3 /CdS/ $\text{Cu}_2\text{ZnSnSe}_4$, indicating that the photostability of CdS can be effectively improved by coverage with an In_2S_3 layer to avoid direct contact of the CdS layer with an electrolyte.

However, for hole-sensitive semiconductors such as ZnO, CdS, and Cu_2O , not only can metal modification accelerate the evacuation of electrons from the semiconductor, but it is also easy to overlook the negative effect of hole accumulation on the stability of these semiconductors. However, the accumulated holes can be consumed in time by the sacrificial agent and/or the reactants in the reaction system, which can suppress the hole-induced dissolution process. However, if the photocorrosion rate caused by accumulated holes is faster than the

rate at which it is consumed by the sacrificial agent and/or reactant, severe photocorrosion of the hole-sensitive semiconductor will occur. In view of this, the photoreaction stability of the hole-sensitized semiconductor can be improved as follows: (i) providing sufficient sacrificial agents or increasing the adsorption capacity of the reactants to improve the rate and efficiency of hole consumption; (ii) introducing a hole-cocatalyst for timely evacuation of holes accumulated in the VB of hole-sensitive semiconductors to prevent hole-induced photocorrosion.

Nevertheless, considering that noble metals are expensive and not readily available, the focus of research has gradually shifted from noble metals to the exploration of low-cost cocatalysts,¹¹⁹ in which earth-abundant transition metals such as Co(II),¹²⁰ Cu(II),¹²¹ and Fe(III)¹²² are considered to be ideal cocatalysts for improving the photoreaction stability of semiconductors. This improved photoreaction stability is attributed to surface-loaded transition metal ions that can act as cocatalysts to accept excited electrons from the semiconductor, thereby inhibiting the recombination of electrons and holes, which in turn improves photocatalytic performance and stability.

4.3.2. Transition metal compound cocatalysts. More recently, loading of transition metal compounds, such as transition metal oxides, sulfides, phosphides, *etc.* on the surface of the semiconductor contributes to an improvement in photocatalytic performance and stability as undesired photo-generated charge carriers can be efficiently evacuated from the semiconductor by the transition metal compound.^{123–125} For example, Grätzel *et al.* demonstrated that the photocorrosion of colloidal CdS solutions was effectively inhibited after loading

with RuO₂ cocatalysts, which was attributed to the fact that RuO₂ can transfer the VB holes of CdS to the aqueous solution in a timely manner for the O₂ evolution reaction, thereby preventing CdS from being oxidized by holes.¹²⁶ Similarly, the study of Maeda *et al.* also showed that the use of RuO₂ as a cocatalyst could inhibit the photocorrosion of GaN:ZnO solid solutions, and as a result, a stable performance for water splitting was obtained under light irradiation.¹²⁷ No obvious difference in the XRD pattern was found between the fresh and used sample, and no Zn²⁺ was detected using the ICP technique in the solution after reaction, demonstrating the excellent stability of RuO₂/GaN:ZnO catalysts. Moreover, long-term durability of GaN:ZnO solid solutions was obtained by loading with Rh_{2-y}Cr_yO₃ NPs, where the oxidative decomposition of GaN:ZnO caused by VB holes was effectively inhibited. Of note, RuO_x as a cocatalyst not only promotes the separation of photogenerated carriers, but also avoids the detachment of the cocatalyst from the electrode since RuO_x has a robust binding. As demonstrated by Tilley *et al.*, the Cu₂O photocathode deposited with RuO_x remained 90% photocurrent intensity of the initial 1 h after 50 h of irradiation, while just 20% was retained with Pt as the cocatalyst under the same conditions, which was due to the stronger binding of RuO_x with the protective layer compared to Pt NPs.¹²⁸

Recently, Yuan and co-workers reported that the photocatalytic activity and stability of CdS nanorods could be improved by loading with Co₃O₄ cocatalysts, where Co₃O₄ accelerated the consumption of VB holes in CdS, resulting in an increase in the number of available photogenerated electrons. As a result, no significant decrease in hydrogen production was found even after three cycles under visible light irradiation with Na₂S–Na₂SO₃ as the sacrificial reagent.¹²⁹ In addition to Co₃O₄, cobalt oxide species CoO_x containing both Co(II) and Co(III) is an emerging cocatalyst for rapidly trapping holes, thereby prolonging the lifetime of photogenerated electrons and holes.¹²⁰ For example, Liu *et al.* prepared CdS/cobalt oxide core-shell nanorods (CdS/CoO_x NRs) by an impregnation-calcination process for photocatalytic hydrogen evolution under a N₂ atmosphere using Na₂S–Na₂SO₃ as the sacrificial agent.¹³⁰ The intimate contact of CdS NRs with the CoO_x shell reduced the interfacial resistance of the VB holes of CdS NRs to the CoO_x shells, and CoO_x as a hole cocatalyst can accept VB holes of CdS NRs, both of which alleviated the hole-induced photocorrosion of CdS semiconductors. As a result, a relatively less decrease in hydrogen production was obtained in the CdS/CoO_x system (38%) (Fig. 8a) compared with single CdS (55%) (Fig. 8b). Unlike PC systems, the separation of the photogenerated charge carriers of the PEC system can be improved by inserting a multifunctional layer underneath the electrochemical catalyst. For instance, Chen *et al.* prepared hierarchical TiO₂@CoNi-layered double hydroxide nanotube arrays (TiO₂@CoNi-LDHs NTAs) for PEC water splitting (Fig. 8c), which exhibited an excellent long-term photocorrosion resistance, with no more than 1.0% loss of the initial activity even after 10 h of irradiation in a Na₂SO₄ electrolyte solution (Fig. 8d and e).¹³¹ This excellent stability was attributed to the fact that the hierarchical structure facilitated the transfer of excited holes toward the LDHs *via* CoII–CoIII, CoIII–O₂, and H₂O oxidation reactions, which in

turn protected the surface from photocorrosion and resulted in improved stability. Vijselaar *et al.* applied a spatioselective method to prepare Si microwire photocathodes with a nickel silicide (NiSi) interlayer between the catalyst and Si microwires.¹³² Such a design facilitated electron transfer to the NiMo catalysts and simultaneously minimized light intervention. As a result, the Si photocathodes achieved a stable performance in strongly alkaline solutions (1 M KOH). Besides, Guo *et al.* reported that stable PEC activity was obtained by the introduction of a Ni/NiO_x bridging layer between NiFe-LDH and Si nanowires, wherein NiO_x with a high ability for hole accumulation and strong binding with NiFe-LDH facilitated the transfer of holes to the catalysts.¹³³ As a result, the NiO_x-containing catalysts achieved long-term stability for 60 h in 1.0 M KOH.

Other transition metal compounds, transition metal sulfides such as MoS₂ (ref. 134 and 135) and WS₂,^{136,137} are also regarded as an inexpensive alternatives to noble metals to improve the activity and stability of semiconductors for solar energy conversion. For instance, Hao's group reported that the photocorrosion of CdS could be effectively inhibited through a photocorrosion-recrystallization process.¹³⁸ A comprehensive analysis of crystallization thermodynamics and kinetics indicated that the establishment of a pathway for the reduction of elemental S to S²⁻ or the design of a new system with a large recrystallization reaction constant (*k*) can inhibit the photo-induced instability of CdS. Since heterogeneous nucleation, especially that of an irregular concave surface, can provide active sites with high nucleation energy compared to homogeneous nucleation, Ma *et al.* designed and prepared a novel CdS/MoS₂ nanocomposite using efficient electron mobility and S vacancies in MoS₂ nanosheets.¹³⁹ The dissociated S elements adsorbed on the surface of the MoS₂ nanosheets can be reduced to S²⁻ using lactic acid as a sacrificial agent. Since MoS₂ nanosheets, especially the edges and defective regions of these sheets, can provide active sites with high nucleation energy and a large *k* value for the crystallization of CdS according to heterogeneous nucleation theory, Cd²⁺ and S²⁻ can recrystallize and CdS grows as solid droplets on the defects and edges of large-scale MoS₂ nanosheets (Fig. 8f). The formation of new CdS NPs in the as-designed CdS/MoS₂ nanocomposites, followed by the photocorrosion-recrystallization pathway, can effectively prevent the photocorrosion process of CdS (Fig. 8g). When the photocorrosion-recrystallization process reached an equilibrium state, a final CdS/MoS₂ nanocomposite with excellent activity and stability was obtained, and the hydrogen evolution rate had no obvious decrease for over 400 h of irradiation (Fig. 8h). Similarly, a CdS/WS₂ photocatalyst was also prepared through the photocorrosion-recrystallization strategy since WS₂ and MoS₂ have extremely similar crystal structures and chemical properties, and as a result, the hydrogen production was maintained at a high level even after irradiation for 200 h.¹³⁸ Similar *in situ* catalyst regeneration is also applied to improve the stability of the PEC system. As reported by the Domen group, the photocurrent remained at a high level up to 400 h for a NiFe oxygen evolution catalyst (OEC)-decorated BiVO₄ photoanode (NiFe-OEC/Mo:BiVO₄/Ni/Sn) with Ni as the contact layer.¹⁴⁰ In contrast, an obvious decrease in the photocurrent

Fig. 8 (a) Stability test of CC-20 and (b) pristine CdS. was detected after 20 h in the NiFe-OEC/Mo:BiVO₄/Ti/Sn photoanode with Ti as the contact layer. This difference in stability was attributed to the self-regeneration of NiFe-OEC by the dissolution of Ni²⁺ in the Ni contact layer, while the Ti contact layer cannot.

As previously described, the oxidative corrosion of hole-sensitive semiconductors can be effectively inhibited by loading with electron cocatalysts; in view of this, MoS₂ might be a good choice. For instance, Yuan and his co-workers prepared core-shell structure MoS₂-ZnO photocatalysts for hydrogen evolution with Na₂S-Na₂SO₃ as the sacrificial agent.¹⁴¹ Only ca. 6% decrease in hydrogen production compared to that of the fresh sample was detected after three cycles, and no difference in the XRD pattern was found between fresh and used MoS₂-ZnO catalysts, indicating an excellent photocatalytic stability for photocatalytic hydrogen production. A similar core-shell

structure was also applied in a ternary photocatalytic system, as reported by Guan *et al.*; the ternary MoS₂-RGO/ZnO composite prepared through a two-step solvothermal pathway exhibited long-term stability for photocatalytic hydrogen evolution with Na₂S-Na₂SO₃ as the sacrificial agent.¹⁴² The stability experiments showed that ca. 93% hydrogen production compared to that of the first cycle was retained after 12 h of reaction, which was much higher than that of single ZnO, indicating improved stability under light irradiation. In order to investigate the difference in structure between fresh and used samples, XRD characterization was carried out. However, no obvious change in the XRD pattern was found before and after reaction for both single ZnO and MoS₂-RGO/ZnO composites, which confirmed the shortcomings of some of the characterization studies described in Section 3. Further XPS analysis of single ZnO can demonstrate the presence of S²⁻ ions, speculating that some of

the ZnO was oxidized by holes to ZnS in the presence of a sulfide sacrificial agent, resulting in a relatively poor photocatalytic stability.

Similar to cobalt oxide species, molybdenum sulfide species MoS_x , a robustly bound co-catalyst, is applied as a cocatalyst to improve the stability of the PEC water splitting system. For instance, Prabhakar *et al.* prepared Sb_2Se_3 - MoS_x catalysts through a low temperature sulfurization process, which had high photocurrent densities and stability in strongly acidic media (1 M H_2SO_4). The improved stability was attributed to the fact that the ionization potential of Sb_2S_3 was higher than that of Se, which resulted in a VB offset at the interface of $\text{Sb}_2\text{S}_3/\text{Sb}_2\text{Se}_3$. This offset acted as a hole-blocking layer to avoid interface recombination, endowing the Sb_2Se_3 thin film with long-term stability in strong acid for 20 h without any photocorrosion.¹⁴³ Morales-Guio reported that a Cu_2O photocathode decorated with MoS_{2+x} exhibited a higher stability compared with the Pt-decorated Cu_2O photocathode in a wide range of pH.¹⁴⁴

Some other transition metal compounds are also regarded as efficient co-catalysts to improve the stability of photocatalytic reactions in semiconductor-based composites. For instance, core-shell $\text{Co}(\text{OH})_2/\text{CdS}$ with $\text{Co}(\text{OH})_2$ decorated with CdS nanowires was prepared by the impregnation synthetic method and exhibited long-term stability for hydrogen evolution, and the hydrogen production was up to $7.52 \text{ mmol h}^{-1} \text{ g}^{-1}$ after irradiation with visible light for 12 h.¹⁴⁵ This stability was attributed to the fact that $\text{Co}(\text{OH})_2$ could effectively consume the CB electrons of CdS to generate Co^+ and Co atoms, resulting in an enhanced charge separation efficiency. Transition metal phosphides are similar to zero-valent metals in properties, which exhibit high activity and stability in PC/PEC water reduction regardless of acid or alkali conditions. In this regard, Cao *et al.* prepared CdS with TMP NP (CoP , Ni_2P and Cu_3P) cocatalysts loaded for photocatalytic hydrogen evolution with L(+)-lactic acid as the electron donor, of which CoP/CdS composites exhibited the highest and most stable performance.¹⁴⁶ The durability tests showed that only a slight decrease in hydrogen production was detected after 50 h of irradiation, suggesting that CoP cocatalysts could greatly improve the photoreaction stability of CdS. In addition, as reported by Cheng *et al.*, FeP/CdS nanorods prepared by grinding showed an excellent stability for photocatalytic hydrogen evolution using lactic acid as a sacrificial reagent.¹⁴⁷ FeP/CdS catalysts with 5% FeP loading showed impressive photochemical stability even after irradiation for up to 100 h. The improved stability was attributed to the band bending between CdS and FeP , which promoted the separation of electron-hole pairs.

Furthermore, recent studies have indicated that metallic Ti_3C_2 can be used as a cocatalyst to improve the mobility of charge carriers within the semiconductors due to the formation of Schottky junctions. In a typical example, Xie *et al.* prepared a two-dimensional (2D) in-plane $\text{CdS}/\text{Ti}_3\text{C}_2\text{T}_x$ sheet-onto-sheet heterojunction, which not only maximized the $\text{CdS}-\text{Ti}_3\text{C}_2\text{T}_x$ interlayer interaction, but also ensured open surface reaction sites for photocatalysis.¹⁴⁸ The stability experiments showed that no significant change in conversion efficiency was found

for $\text{CdS}/\text{Ti}_3\text{C}_2\text{T}_x$, while a significant decrease was detected for single CdS (Fig. 9a). The S 2p XPS peak showed that the polysulfide ratio of CdS (26.0%) was higher than that of $\text{CdS}/\text{Ti}_3\text{C}_2\text{T}_x$ (17.1%) (Fig. 9b), suggesting the retarded light-induced instability of CdS by the modification of $\text{Ti}_3\text{C}_2\text{T}_x$, which can also be proved by Cd^{2+} leakage (Fig. 9c). This enhanced photostability was attributed to the strong interaction between Cd^{2+} and $\text{Ti}_3\text{C}_2\text{T}_x$. The Cd^{2+} released by CdS photocorrosion were *in situ* confined on the interlayer interacted $\text{Ti}_3\text{C}_2\text{T}_x$, which was demonstrated by the Cd^{2+} adsorption results (Fig. 9d). As a result, not only could Cd^{2+} leaching be effectively prevented, but the surface reaction sites were also not damaged. Furthermore, given that one-dimensional (1D) nanostructures with high length-to-diameter ratios are in favor of light adsorption and charge transfer, Xiao and co-workers prepared 1D CdS nanorod/2D Ti_3C_2 heterojunctions with interfacial coupling for photocatalytic hydrogen evolution.¹⁴⁹ It was found that the photocatalytic activity and stability of CdS with respect to hydrogen evolution were obviously improved after the introduction of Ti_3C_2 , with negligible decrease in hydrogen production after five cycles. This enhanced activity and stability was attributed to the fact that the Schottky junction at the interface of CdS and Ti_3C_2 can accelerate charge separation and transfer within CdS nanorods.

4.3.3. Molecular complex cocatalysts. In order to further develop high-efficiency cocatalysts to obtain catalysts with high photocatalytic performance and stability, increasing the active site of the catalytic reaction and promoting the transfer of charge carriers at the interfaces are also effective strategies for improving the photoreaction stability, which can be achieved by decreasing the size of the cocatalyst.¹⁵⁰ Numerous studies have shown that molecular cocatalysts are employed in combination with semiconductors to construct composite photocatalysts with high stability for target photocatalytic reactions. For example, Zhao *et al.* anchored well-dispersed $\text{Co}(\text{II})/\text{Ni}(\text{II})$ species on the CdS surface by controlling the decomposition of Co/Ni -EDTA precursors at 300 °C (CdS-CoE-300) and 350 °C (CdS-NiE-350) with $\text{Na}_2\text{S}-\text{Na}_2\text{SO}_3$ as the sacrificial agent.¹⁵¹ Scanning transmission electron microscope (STEM) images showed that Co and Ni elements were uniformly dispersed in the form of a thin amorphous layer on the surface of CdS-CoE-300 and CdS-NiE-350 , respectively (Fig. 9e). CdS-CoE-300 with a molar ratio of Co-EDTA to CdS of 1.4% showed a relatively high hydrogen production of 2.7 mmol h^{-1} . Loading with Co-EDTA cocatalysts of 0.7% mole ratio realized the highest the hydrogen production of 3.1 mmol h^{-1} , and the turnover frequency (TOF) was as high as 600 h^{-1} . The stability experiments showed that no significant decrease in hydrogen production was found after six cycles (Fig. 9f): a hydrogen production of 2.8 mmol h^{-1} was obtained even after irradiation under sunlight for one month, demonstrating a long-term and stable performance for hydrogen evolution. However, the CdS-NiE sample calcined at 350 °C exhibited the optimal performance for hydrogen evolution, with a hydrogen production of 4.3 mmol h^{-1} and TOF up to 864 h^{-1} . Similar to CdS-CoE-300 , CdS-NiE-350 also exhibited excellent stability, as demonstrated by cycling experiments and the hydrogen production

under long-term sunlight irradiation (Fig. 9g). The excellent photocatalytic stability of CdS-CoE-300 and CdS-NiE-350 was due to surface sulfur passivation and efficient charge transfer from CdS to Co(II) or Ni(II).

4.3.4. Dual cocatalysts. A large number of existing studies have demonstrated that the loading of dual cocatalysts (electron and hole cocatalysts) can effectively overcome the photo-induced instability of semiconductor-based catalysts. In a dual cocatalyst supported semiconductor composite photocatalytic system, the photogenerated electrons and holes are respectively transferred to the reduction and oxidation cocatalysts, which results in efficient charge spatial separation, thereby improving the photocatalytic performance and stability. Generally, noble metal cocatalysts, such as Ag, Pt, Au *etc.*, are usually employed as hydrogen evolution cocatalysts due to their excellent electron acceptability, while some metal oxides/sulfides, such as RuO₂, CoO_x, PdS *etc.*, are employed as oxygen evolution catalysts. For example, Yang *et al.* reported that Pt and PdS dual cocatalyst-supported CdS exhibited high and stable photocatalytic hydrogen evolution performance under visible light irradiation with Na₂S-Na₂SO₃ as the

sacrificial reagent.¹⁵² For single CdS, an obvious decrease in hydrogen production was detected after 10 h of irradiation owing to hole-induced photocorrosion. However, in the case of Pt-PdS/CdS, a stable hydrogen evolution was obtained for at least 25 h, demonstrating an enhanced photocatalytic stability after loading with Pt-PdS dual cocatalysts, as demonstrated by no difference in the XRD pattern (Fig. 9h) and TEM image (Fig. 9i) between the fresh and used sample. What is more, Pt-PdS dual cocatalysts exhibited a similar role in hydrogen evolution for other metal sulfide semiconductors, such as ZnO_{1-x}S_x, ZnIn₂S₄, ZnGa₂S₄, and (CuIn)_{0.8}Zn_{1.82}S (Fig. 9j). However, in most cases, a cocatalyst is deposited on the surface of the photocatalyst by an impregnation or adsorption method, which results in uncontrolled surface distribution of the cocatalyst. To achieve the selective deposition of cocatalysts, facet engineering provides a feasible strategy since photo-generated electrons and holes are enriched in different crystal facets of the facet-dependent semiconductor. As a typical example, dual-cocatalysts, Pt and Co₃O₄, are selectively deposited on the (010) and (110) facets through the photo-deposition method, respectively.¹⁵³ The prepared Pt/Co₃O₄/BiVO₄ catalysts

exhibited a high and stable performance for oxygen evolution with IO_3^- as the electron acceptor under visible light irradiation. Such a stability was due to the fact that the oxidation and reduction reactions were carried out independently on different facets, greatly maximizing the redox ability of photogenerated holes and electrons.

From an economic point of view, the replacement of precious metals with alternative rich non-precious metal promoters is in line with the concept of sustainable development. For instance, Yu' group prepared dual amorphous TiO_2 and Ni(II) co-modified CdS catalysts (Ti(IV)-Ni(II)/CdS) for hydrogen evolution using $\text{Na}_2\text{SO}_3\text{-Na}_2\text{S}$ as the sacrificial reagent under visible light irradiation.¹⁵⁴ Cycling tests showed that as the cycles increased, the hydrogen production of a single CdS decreased gradually, while Ti(IV)-Ni(II)/CdS maintained a high stable hydrogen evolution under identical conditions, suggesting that the stability of CdS was improved with the co-modification with amorphous Ti(IV) and Ni(II) . This excellent stability was due to the fact that the holes could be consumed in a timely manner by the hole-cocatalyst Ti(IV) , resulting in more available photogenerated electrons participating in the hydrogen evolution reaction.

4.4. Hybridization with carbon-based materials

Carbon-based materials, such as graphene, reduced graphene oxide (rGO), carbon nitride or carbon quantum dots, are considered to be ideal electron acceptors and transporters due to their high chemical stability and excellent electrical conductivity.¹⁵⁵ Hence, constructing carbon-based-semiconductor photocatalysts is a feasible method to promote charge separation, thereby preventing the photocorrosion caused by charge carriers under light irradiation.

4.4.1. Graphene and its derivatives. Graphene is a 2D honeycomb structured carbon material obtained by organizing atomic sheets of sp^2 bonded carbon atoms, which has aroused research interests. Most importantly, the superior electrical conductivity and the springy atom-thin 2D features of graphene make it an excellent electron-transport matrix, which is also particularly useful for preventing surface oxidation of metals and semiconductors. For instance, Wang *et al.* used layered graphene (LG) as a protecting layer to improve the stability of the CdS film, which exhibited an 8-fold increase in the effective lifetime under visible light irradiation compared with single CdS.¹⁵⁶ About 11, 24, 46, and 88 min of irradiation were needed for photocurrent density reduction to $0.5 \mu\text{A cm}^{-2}$ for CdS, CdS/1LG, CdS/2LG, and CdS/3LG, respectively (Fig. 10a). This difference was due to the varying degrees of photocorrosion of CdS, which could also be proved by the color change of samples after irradiation (Fig. 10b). XPS characterization demonstrated the presence of S^{6+} in CdS after irradiation for 10 min, whereas not S^{6+} but S^0 was detected in CdS/3LG after 30/60 min, demonstrating that single CdS was oxidized to SO_4^{2-} by excited holes with the participation of oxygen or water molecules but CdS/3LG was directly oxidized by holes. To investigate the role of graphene, DFT calculations were carried out. Barrier energies of 111.2 and 37.4 eV were needed for O_2 molecules to

perpendicularly pass through the bridge and hollow sites of graphene. Even after graphene was changed to defective graphene, 13.9 eV barrier energy was also needed. Moreover, H_2O molecules exhibited a similar result, both of which were energetically unfavorable. Therefore, draping CdS with layered graphene can effectively prevent the direct contact of CdS with O_2 and H_2O .

Graphene derivatives with properties similar to those of graphene have also been shown to improve the photostability of metal sulfides. For example, Jia *et al.* bridged CdS nanocrystals with N-graphene nanosheets to prepare N-graphene/CdS photocatalysts, in which N-doped graphene (N-graphene) acted as an electron transfer channel to reduce the recombination of the photogenerated electron-hole pairs.¹⁵⁷ Therefore, the photocatalytic performance for water splitting did not show any significant decrease after the reaction for longer than 30 h, indicating improved stability in the N-graphene/CdS composite. What is more, Tran *et al.* reported that rGO could consume the photogenerated electrons of Cu_2O in a timely manner, thereby preventing Cu_2O from being reduced to Cu.¹⁵⁸ As a result, a high and long-term stability of hydrogen evolution was obtained in the $\text{Cu}_2\text{O-rGO}$ composite. Similarly, Zhang *et al.* demonstrated that the photo instability of Cu_2O concave cubes with oxygen vacancies could be effectively inhibited by the modification of RGO.¹⁵⁹ The prepared $\text{Cu}_2\text{O-RGO}$ catalysts still exhibited a stable photocatalytic performance for hydrogen evolution after three recycles with methanol (20%) as the sacrificial agent under 300 W Hg lamp irradiation, which was due to the fact that RGO and oxygen vacancies can effectively transfer photogenerated electrons and prevent the recombination of electron-hole pairs. In another example, Zhang *et al.* prepared the RGO-ZnCdS composite through a coprecipitation hydrothermal reduction process for photocatalytic hydrogen evolution with $\text{Na}_2\text{S-Na}_2\text{SO}_3$ as the sacrificial agent under simulated solar irradiation.¹⁶⁰ Cycling tests showed that no detectable decrease in hydrogen production was found in RGO-ZnCdS composites after four cycles. However, in the case of single ZnCdS, hydrogen production gradually decreased as the cycles increase. Such an enhanced stability was due to the fact that the photogenerated electrons of ZnCdS were transferred to RGO, thereby preventing ZnCdS from being reduced by photogenerated electrons.

To date, most investigations regarding graphene-based materials focus on the immobilization of nanoparticles on graphene sheets. However, in the case of a PEC system, the one-dimensional (1D) nanostructures such as nanowire arrays (NWAs) or nanotubes are more favored since their unique morphology can offer a direct path for charge carrier transfer, with reduced grain boundaries and high crystallinity, resulting in superior charge transfer ability. For instance, Dubale *et al.* prepared a 1D-nanocomposite electrode of graphene/ Cu_2O NWA/Cu mesh combining electrochemical anodization, dip coating and annealing process (Fig. 10c).¹⁶¹ The photocurrent density of the G-1.0/ $\text{Cu}_2\text{O}/\text{Cu}$ mesh at the end of 20 min exhibited more than five-fold enhancement in photostability (83.3%) compared to the bare $\text{Cu}_2\text{O}/\text{Cu}$ mesh (14.5%), demonstrating that graphene exhibited an excellent behavior in suppressing photocorrosion of Cu_2O and could be used to accelerate

the transfer of photogenerated carriers and lower the recombination of electrons and holes. Furthermore, SEM (Fig. 10d) and XRD analysis showed that Cu NPs over the surface of the Cu₂O/Cu mesh sample could be observed, while it was absent for graphene modified Cu₂O, suggesting that the incorporation of graphene exhibited interesting protection towards inhibiting photocorrosion of Cu₂O, thereby resulting in an enhanced photocurrent density and stability under light irradiation.

4.4.2. Graphitic carbon nitride. Graphitic carbon nitride (g-C₃N₄) with good durability in varied chemical environments has been widely investigated in the field of PC and/or PEC. The construction of g-C₃N₄-based composites is an effective strategy to improve the corrosion resistance of semiconductors under visible light irradiation. Considering that the VB potential of CdS is lower than that of g-C₃N₄, theoretically, the VB holes of CdS can be transferred to g-C₃N₄, thereby preventing the hole-

induced photocorrosion of CdS. Inspired by this, Zhang *et al.* prepared core-shell CdS/g-C₃N₄ nanowires for photocatalytic hydrogen evolution with Na₂S and Na₂SO₃ as sacrificial reagents under visible light irradiation.¹⁶² Cycling experiments exhibited that the hydrogen production of CdS/g-C₃N₄ was maintained at a high level after four cycles, suggesting the superior stability. ICP technology was employed to evaluate the dissolution of CdS, and the results showed that the concentration of released Cd²⁺ in solution after reaction for 8 h was 329.23 and 29.04 mg L⁻¹ for CdS and CdS/g-C₃N₄, respectively, suggesting less dissolution in CdS/g-C₃N₄ composites. Moreover, the TEM image of the used sample showed that CdS/g-C₃N₄ well retained its morphology and crystal structure, while serious aggregation was found in used CdS; the above results all indicated that the modification of CdS with g-C₃N₄ could result in long-term stability for hydrogen evolution.

4.4.3. Other carbon materials. Other carbon materials such as amorphous carbon, fullerene (C₆₀), carbon nanofibers, graphite-like carbon, carbon nanotubes and carbon dots are also good candidates to improve the photostability of semiconductors.^{156,163} For instance, carbon nanofibers were *in situ* grown on the surface of ZnIn₂S₄ (CNF@ZnIn₂S₄) through a two-step method for photocatalytic hydrogen generation using Na₂S–Na₂SO₃ as the sacrificial reagent under visible light irradiation.¹⁶⁴ Compared with single ZnIn₂S₄, CNF@ZnIn₂S₄ exhibited high and stable hydrogen production, and no obvious drop in hydrogen production was detected after four cycles. This enhanced stability was due to the vector transfer of the electrons from ZnIn₂S₄ to carbon nanofibers, which effectively prevented the reduction of In³⁺ and Zn²⁺, resulting in enhanced stability. In another example, Kim *et al.* prepared ideal quasi-core-shell quantum dot structures composed of ZnO–graphene and ZnO–C₆₀ through a simple chemical process for photocatalytic water oxidation (Fig. 10e).¹⁶³ Due to the good conductivity of graphene/C₆₀, the excited electrons in the VB of ZnO can be efficiently transferred to graphene/C₆₀, leaving the holes in the VB of ZnO. In addition, the strong Zn–O–C bond existing between the ZnO core and nanocarbon shell prevented photo-generated holes from being consumed by the photocorrosion reaction of ZnO, resulting in improved photocatalytic stability (Fig. 10f).

For PEC systems, coating the semiconductor with an inert protective layer to avoid direct contact of the electrode and the electrolyte is an effective method to relieve photocorrosion. However, the inert protective layer has poor conductivity, which limits the transfer of charge carriers. Therefore, carbon-based materials with high electrical conductivity are a good substitute for the inert protective layer to enhance the stability and activity of PEC systems. Since both photoreduction in the presence of photogenerated electrons or photooxidation by the consumption of holes will lead to the photocorrosion of Cu₂O, the high conductivity of the carbon-based material makes it possible to effectively withdraw the excited electrons away from Cu₂O to suppress the photoreduction reaction of Cu₂O. In addition, the carbon sheath can also indirectly protect Cu₂O from being oxidized to CuO. Therefore, coating a carbon-based protecting layer on Cu₂O thin films is a theoretically feasible

strategy to inhibit the photocorrosion of Cu₂O. For example, Zhang *et al.* used glucose as the carbon precursor to form a protective carbon coating onto Cu₂O NWAs through a simple solution-based process (Fig. 10g).¹⁶⁵ The carbon layer with a thickness of 20 nm exhibited optimal performance and stability for water splitting, with more than 6-fold photostability improvement for C-3/Cu₂O NWA/Cu compared to the non-carbon protected Cu₂O NWA/Cu mesh photocathode, as illustrated in the stability evaluation (Fig. 10h). In addition, the long-term stability test showed that only 25% decrease of the original photoactivity was detected in the C-3/Cu₂O NWA/Cu mesh while 100% loss was found for the Cu₂O NWA/Cu mesh after 1 h of irradiation, and no copper particles can be identified in the SEM image of used C-3/Cu₂O NWA/Cu while some copper particles were found from the SEM image of used Cu₂O NWA/Cu, suggesting that the stability of Cu₂O can be effectively improved by coating with a carbon protective layer.

Moreover, since the self-photooxidation of Cu₂O occurs in the presence of hydroxyl ions (OH⁻), preventing the Cu₂O particles from directly coming into contact with the solvent or the electrolyte can inhibit the photocorrosion of Cu₂O. In this case, the hydrophobicity of the carbon material plays an important role in protecting the particles. For instance, Yu *et al.* prepared carbon layer coated Cu₂O mesoporous nanorods on Cu foil through a facile chemical oxidation and subsequent carbonization process.¹⁶⁶ Only 7% loss compared to the first run was found after six cycles, while 46% decrease was detected for single Cu₂O, indicating the good photostability of Cu₂O after modification with the carbon layer. The SEM image of Cu₂O and C-2/Cu₂O after three cycles and six cycles showed that Cu₂O tended to agglomerate and fuse after six cycles; in the case of C-2/Cu₂O, only a slight increase in size was found and the 1-D nanorod structure remained well, suggesting superior structure stability, which can also be demonstrated from the XPS spectrum of Cu 2p and surface X-ray diffraction (SXRD) results. As a result, the gradually passivated thin carbon layer acted as a protective layer of Cu₂O to greatly improve its photoreaction stability.

4.5. Construction of heterojunctions

One of the factors limiting the photocatalytic performance and stability of single semiconductors is the rapid recombination of photogenerated electrons and holes. Numerous studies have shown that the construction of a heterojunction structure can greatly accelerate the separation of photogenerated electrons and holes. At present, research toward heterojunction construction is mainly concentrated on type-I, type-II, Z-scheme, and p–n heterojunctions, which will be elaborated in detail with convincing examples in the following section.

4.5.1. Type I heterojunction. A typical feature of a type I heterojunction is that the CB and VB edges of one semiconductor are above/below those of the other semiconductor. When the two semiconductors are in intimate contact to form a contact interface, photogenerated electrons and holes are respectively accumulated in the CB and the VB of the narrow bandgap semiconductor due to band mismatch. For instance,

a type I CdS@MoS₂ heterojunction composite was prepared for photocatalytic hydrogen evolution with lactic acid as hole sacrificing agent, where the surface of 1D CdS nanowires was coated with multilayered MoS₂ nanosheets.¹⁶⁷ Cycling experiments showed that about 30.8% and 19.8% decrease in hydrogen evolution was detected for CdS and CdS@MoS₂, respectively. The relatively higher stability of CdS@MoS₂ was attributed to the unique structure of the type I junction generated at the interface of CdS and MoS₂, in which the excited electrons and holes of CdS were spontaneously transferred to the corresponding CB and VB of MoS₂ due to energy level mismatch. Since MoS₂ possessed inferior recombination rates of photogenerated holes and electrons, such a type I junction can effectively inhibit the oxidation or leaching of CdS, thereby resulting in improved photocatalytic stability. In addition, no apparent peak belonging to S⁰ was identified in the S 2p XPS spectrum of the used CdS@MoS₂ sample, and no difference in morphology between fresh and used CdS@MoS₂ catalysts was found from SEM image, indicating that the MoS₂ protective layer not only improved the photocatalytic performance of CdS, but also resulted in an enhanced photocatalytic stability. A similar type-I core-shell composite was also prepared by Xie *et al.*, in which a mesoporous ZnS shell was *in situ* grown on a CdS core through a one-pot surfactant-free hydrothermal route.¹⁶⁸ Compared with single CdS and ZnS, the CdS-ZnS composites exhibited high and stable hydrogen evolution, and 87% hydrogen production of the fresh sample was maintained after the sixth cycle (60 h) without renewing the sacrificial agents. As shown in Fig. 11a, a type-I heterojunction was generated in the CdS@ZnS composite based on the analysis of the band edges of CdS and ZnS, which indicated that the CB electrons and VB holes of CdS were thermodynamically difficult to transfer to the ZnS shell under visible light irradiation. However, the photo-deposition of Pt has demonstrated that the VB holes and CB electrons were located in the ZnS shell and CdS core, respectively. Therefore, a possible explanation was that the inherent defects of ZnS such as zinc vacancies (V_{Zn}) and interstitial sulfur (I_S) were in localized acceptor states to accept VB holes of CdS, which was similar to the electron injection pathways in dye-sensitized solar cells. As a result, the VB holes of CdS were effectively transferred to V_{Zn} or I_S, leaving the photo-generated electrons in the CB of CdS, thereby preventing the hole-induced photocorrosion of CdS Fig. 11b. As reported by Bandara and co-workers, a CuO incorporated TiO₂ composite was synthesized for photocatalytic hydrogen evolution with methanol as the sacrificial agent under UV light irradiation.¹⁶⁹ The prepared TiO₂/CuO catalysts showed excellent photocatalytic performance and stability and just a slight decrease in hydrogen production was found after five cycles. This stability was attributed to rapid interparticle electron transfer and efficient hydrogen evolution reaction which retarded the dissolution of CuO catalyst under light irradiation.

However, the structural features of type I heterojunctions cause the photogenerated electrons and holes of the wide band gap semiconductor to be transferred to the corresponding CB and VB of the narrow band gap semiconductor, which results in a sharp decrease in the number of photogenerated carriers

available for surface redox reactions. In view of this, how to promote the transfer of charge carrier from the core to the outer surface is the key to realize the application of type I core/shell nanocrystals in PC/PEC water splitting systems. To this end, type II heterojunctions come into being.

4.5.2. Type II heterojunction. In type II heterojunction, the CB and VB positions of the semiconductor I are higher/lower than those of semiconductor II, which causes photogenerated electrons to be transferred from a semiconductor with a high CB potential to another one, while the holes are simultaneously transferred in the opposite direction. Therefore, electrons and holes are separated in two individual semiconductors, resulting in improved photocatalytic performance and stability. For instance, Yu *et al.* prepared ZnFe₂O₄ decorated CdS nanorods by a solvothermal method for photocatalytic hydrogen evolution with Na₂S-NaSO₃ as the sacrificial agent under visible light irradiation.¹⁷⁰ As shown in Fig. 11c, ZnFe₂O₄ with a size of 10 nm adhered to the surface of CdS nanorods to form intimate interfaces, which facilitated the charge transfer between ZnFe₂O₄ and CdS. Cycling tests showed that the hydrogen production rates improved with the increase in reaction time for ZnFe₂O₄/CdS composites after four cycles Fig. 11d. However, in the case of single CdS, a significant decrease in hydrogen production was detected under the same conditions. Comparing the morphology before and after reaction, the structure of single CdS was severely damaged due to photo-corrosion (Fig. 11e), while ZnFe₂O₄/CdS composites remained intact without any damage after four successive cycles (Fig. 11f). The stable photocatalytic performance was due to the type II charge transfer mechanism at the interface of ZnFe₂O₄ and CdS, in which the photogenerated electrons of ZnFe₂O₄ were transferred to the CB of CdS, while VB holes of CdS were effectively transferred to the VB of ZnFe₂O₄ due to energy band alignment, which greatly prevented CdS from being oxidized by its VB holes.

Nowadays, (oxygen) nitrides are reported as a promising material for solar energy conversion owing to their wide visible light absorption, suitable CB/VB position, and excellent photostability. As reported by Dong *et al.*, a 0D/1D Ta₃N₅/BaTaO₂N heterostructure was prepared by an ammonia thermal synthesis process with KBa₂Ta₅O₁₅ as the precursor, in which BaTaO₂N NPs were *in situ* grown on the surface of Ta₃N₅ nanorods.¹⁷¹ Due to a type-II heterostructure formed between Ta₃N₅ and BaTaO₂N, the CB electrons of BaTaO₂N with a relatively high CB potential were transferred to the CB of Ta₃N₅, while the VB holes of Ta₃N₅ were transferred to the VB of BaTaO₂N, resulting in the accumulation of photogenerated electrons and holes in two individual semiconductors. As a result, the prepared Ta₃N₅/BaTaO₂N composites exhibited a high and stable photocatalytic performance for water splitting, and no significant drop in H₂/O₂ production was found after five cycles (150 h).

Moreover, since the stability of semiconductor is also dependent on its structural design, the combination of morphology engineering and a type II heterojunction can achieve composite catalysts with improved stability. As a typical example, a lollipop-shaped uniform Cu@Cu₂O/ZnO composite with ultra-small Cu@Cu₂O NPs partially coated with ZnO

nanorods was designed through a hot-injection synthesis process for photocatalytic hydrogen evolution with Na₂S–Na₂SO₃ as the sacrificial agent under UV-vis irradiation.¹⁷² Cycling experiments showed that Cu@Cu₂O/ZnO composites maintained a stable hydrogen production after more than 8 h of irradiation. The excellent stability was attributed to the formation of type-II heterojunction between Cu@Cu₂O and ZnO, in which ZnO nanorods were selectively epitaxially grown on the

(111) facets of Cu nanocrystals, resulting in partial coating of the Cu@Cu₂O NPs with ZnO, thereby preventing the surface oxidation of Cu NPs. Moreover, facet-dependent properties also play important roles in photostability improvement due to the influences towards charge transfer efficiency. Based on the partial density of states (DOS) (Fig. 11g), Li *et al.* found that there were 80 meV and 60 meV band offsets of the CB and VB for the (001) facets relative to the (101) facets of Cu₂WS₄, which

indicated that a type-II staggered band alignment formed between these two facets, resulting in the photogenerated electrons and holes being accumulated in the (001) and (101) facets (Fig. 11h).¹⁷³ Photocatalytic hydrogen evolution performed in the presence of S^{2-} or S^{2-}/SO_3^{2-} can maintain the smooth (101) facets; however, an obvious corrosion on the (101) facets can be detected with only Na_2SO_3 as the sacrificial agent. This difference was determined by whether the holes accumulated in the (101) facets can be consumed in a timely manner by S^{2-} (Fig. 11i). Therefore, the photooxidative etching caused by the holes can be avoided by decreasing the ratio of the (101)/(001) crystal facets.

4.5.3. Z-Scheme heterojunction. Although a type-II heterojunction can achieve efficient charge separation through energy band alignment, it is at the expense of the redox capability of the photogenerated carriers. Z-Scheme photocatalytic systems that can efficiently widen the optical absorption range, facilitate charge separation, and maximize the redox ability of photogenerated carriers are a promising alternative to traditional type-II heterojunctions to achieve high and stable visible light photocatalytic performance. In the Z-scheme system, the photoexcited electrons with a lower CB potential in one semiconductor are recombined with the holes with a higher VB potential in the other semiconductor in the presence/absence of a mediator, which not only facilitates the separation of photogenerated electron-hole pairs, but also retains the strong redox ability of electrons and holes.¹⁷⁴ Considering these advantages, an increasing number of studies are focused on constructing semiconductor-based Z-scheme photocatalytic systems to achieve a long-term and robust photocatalytic performance, and some breakthroughs have been made. At present, three generations of Z-scheme photocatalytic systems have been developed, including redox-mediator, all-solid-state and direct Z-scheme photocatalytic systems.¹⁷⁵ Considering that the redox-mediator Z-scheme photocatalytic system can only be used in the liquid phase and is largely affected by the reaction environment, the latter two Z-scheme heterojunctions are more widely investigated.

An all-solid-state Z-scheme photocatalytic system consists of two isolated photochemical systems and a mediator, in which the mediator promotes charge carrier transfer at the contact interface. A typical all-solid-state Z-scheme photocatalytic system, CdS-Ag-TiO₂, was constructed by Zhao *et al.* through a solvothermal process for hydrogen evolution under xenon lamp irradiation, in which Ag NPs and TiO₂ quantum dots were successively deposited on the surface of CdS nanowires.¹⁷⁶ The recycling test showed that CdS-Ag-TiO₂ exhibited the highest stability with no obvious decrease in hydrogen production after four cycles, while nearly 43% loss in hydrogen production was detected for the CdS-TiO₂ composite. The poor stability of CdS-TiO₂ was attributed to the fact that the excited holes of CdS still remained in the VB of CdS, thereby resulting in hole-induced photocorrosion in the CdS-TiO₂ system. Conversely, the VB holes of CdS can be consumed in a timely manner by the CB electrons of TiO₂ through the Ag mediator, which not only prevented the hole-induced photocorrosion of CdS, but also left more available photogenerated electrons to participate in the

hydrogen evolution reaction. Besides noble metals, readily available and inexpensive media are more environmentally friendly. For example, Wang *et al.* prepared a ZnO-CdS@Cd heterojunction with the Cd core coated with a ZnO-CdS shell for photocatalytic hydrogen evolution using Na₂S-Na₂SO₃ as the sacrificial agent.¹⁷⁷ The prepared ZnO-CdS@Cd exhibited long-term stability without any decrease in hydrogen production after four cycles (20 h). In addition, no change in binding energies of Zn 2p, Cd 3d, and O 1s XPS spectra was found in the used ZnO-CdS@Cd catalyst, and ZnO-CdS@Cd retained a stable morphology after photocatalytic reactions for 20 h. This stable hydrogen evolution performance was due to the following: (i) the CB electrons of ZnO can effectively recombine with the VB holes of CdS through the Cd core mediator, resulting in a prolonged lifetime; (ii) the thin ZnO-CdS shell (15 nm) was able to shorten the diffusion length of charge carrier transport in ZnO-CdS@Cd to hinder the bulk recombination of charge carriers in ZnO or CdS.

More recently, the direct Z-scheme photocatalytic system that omits the process of carriers passing through the electron mediator has attracted widespread concern since Wang *et al.* constructed the first mediator-free all-solid-state Z-scheme photocatalytic system in 2009.¹⁷⁸ Subsequently, more research has been focused on the design and construction of direct Z-scheme photocatalytic systems for widespread application. In a typical example, a CdS/BiVO₄ composite with CdS NPs decorated on 1D BiVO₄ nanowires was prepared by Zhou and co-worker, which exhibited a high and stable performance for photocatalytic hydrogen evolution with lactic acid as the hole scavenger and Pt as the cocatalyst under visible light irradiation.¹⁷⁹ The photocatalytic hydrogen production experiments of Pt/CdS and CdS/BiVO₄ in Na₂SO₃ electrolyte showed that a significant decrease (53%) in hydrogen production was found in the presence of Pt/CdS after five cycles (300 h), while only 17% decrease of hydrogen evolution in the first cycle was detected over CdS/BiVO₄, indicating that the oxidation sites were located at BiVO₄ instead of CdS. Due to the formation of the Z-scheme heterojunction, the VB holes of CdS can recombine with the CB electrons of BiVO₄, which not only retained the strong redox ability of photogenerated charge but also effectively prevented CdS from being oxidized by its holes, thereby resulting in an excellent photocatalytic performance and stability.

In addition, Ma *et al.* applied atomic layer deposition (ALD) technology to prepare a CdS@ZnO composite with controlled morphology and distribution of the ZnO shell for photocatalytic hydrogen evolution with Na₂SO₃-Na₂S as the sacrificial agent under 225 W Xe arc lamp irradiation.¹⁸⁰ Long-term recycling investigation showed that the hydrogen production of Pt-deposited CdS@ZnO catalysts did not change after five cycles, and a stable crystal structure was obtained after multiple cycles, as demonstrated by the XRD pattern. Moreover, ICP was applied to investigate the leaching of Cd²⁺ ions; the results showed that only 0.01 mg L⁻¹ Cd²⁺ was detected for Pt-deposited CdS@ZnO after 8 h of irradiation, while 1.39 mg L⁻¹ Cd²⁺ was detected for Pt/CdS under the same conditions, indicating that the modification with the ZnO shell can effectively prevent CdS from being

photo-corroded. The stable photocatalytic performance was due to the Z-scheme charge transfer mechanism between CdS and ZnO, resulting in photogenerated electrons accumulating in the CB of CdS while holes accumulated in the VB of ZnO. In this case, ZnO also might be oxidized by accumulated holes, as demonstrated by ICP results. Therefore, the hole cocatalyst PdS was *in situ* deposited on the surface of ZnO for timely capture of the VB holes of ZnO, which exhibited an improved stability and activity toward photocatalytic hydrogen evolution. In another work, a ZnO–CdS core–shell heterojunction with 0D CdS NPs coated on the surface of 1D rod-like ZnO was fabricated for photocatalytic hydrogen evolution with Na_2S – Na_2SO_3 as the sacrificial agent under 300 W Xe lamp irradiation (Fig. 12a).¹⁸¹ Cycling experiments showed that no obvious decrease in

hydrogen production was found after three cycles (30 h) regardless of ZnO@CdS or RuO_2 -deposited ZnO@CdS, indicating a high and long-term stable performance for photocatalytic hydrogen evolution. The stability was attributed to the charge transfer between ZnO and CdS following the Z-scheme mechanism, in which the photogenerated electrons in the CB of ZnO recombined with the holes of CdS, leaving electrons in the CB of CdS involved in the hydrogen evolution reaction.

Considering that creating a specific and favorable interface can promote the directional transfer of charge carriers, if the polar (002) facets of ZnO serve as active sites, the heterojunction bonded on these active sites might facilitate the separation of charge carriers. In this regard, Ma *et al.* investigated the synthesis and properties of both selectively and randomly

distributed ZnO/CdS heterostructures for photocatalytic hydrogen evolution with $\text{Na}_2\text{S}-\text{Na}_2\text{SO}_3$ as the sacrificial agent under irradiation with a 300 W Xe lamp.¹⁸² The results indicated that ZnO/CdS with selective distribution of heterostructures around the pores exhibited a higher photocurrent response and lower electrochemical impedance than those of ZnO/CdS with randomly distributed heterostructures. Due to the Z-scheme, the ZnO/CdS heterostructure was selectively fabricated at the active pores, resulting in more efficient charge separation, higher hydrogen evolution and stability for the ZnO/CdS heterostructure.

4.5.4. Homojunctions. In addition to forming a heterojunction with a foreign semiconductor, the construction of homojunctions/phase junctions between different crystal phases of a single semiconductor is also a viable method to improve the photoreaction stability of single-phase semiconductors and also to avoid incompatibility between different semiconductors present in heterostructures.¹⁸³ In a homojunction system, an internal field is formed between two different crystal phases due to the well-matched interfaces and favorable band alignments, which facilitate the separation of photogenerated electron-hole pairs, thereby resulting in a high photocatalytic performance and stability.¹⁸⁴ For instance, since a built-in electric potential at the hexagonal-cubic CdS interface can lower the possibility of bulk recombination of photogenerated electrons and holes, thereby further improving solar-to-fuel conversion efficiency, Ai *et al.* designed a CdS phase junction nano-photocatalyst, with a controllable bonding region width between the cubic phase and hexagonal phase for photocatalytic hydrogen evolution with lactic acid as the sacrificial agent (Fig. 12b).¹⁸⁵ The prepared CdS phase junction maintained a high and stable performance for photocatalytic hydrogen evolution after 100 h of reaction (Fig. 12c), and only 20% decrease in hydrogen production was detected even after irradiation for 150 h, while CdS without a phase junction underwent photocorrosion within 11 h (Fig. 12d), indicating that the formation of phase junction effectively improved the photocorrosion resistance of CdS. In addition, the suitable bonding region width can act as a shield for the phase junction, thereby resulting in a long photocatalytic lifetime, as demonstrated by the stable HRTEM (Fig. 12e) and XRD results (Fig. 12f) after 100 h of reaction.

To further improve the long-term stability of CdS-based phase junctions, efforts and interest have further focused on the application of structural engineering in the phase-junction design. For example, Li *et al.* prepared concentric CdS nanorod phase junction (NRPJ) integrated hexagonal-cubic core-shell architecture with a nanorod morphology through the hydrothermal process for photocatalytic hydrogen evolution with $\text{Na}_2\text{S}-\text{Na}_2\text{SO}_3$ as the sacrificial agent and a 300 W Xe arc lamp as the light source.¹⁸⁶ The formation mechanism of the hexagonal/cubic CdS phase junction was investigated by optimizing the ratio of Cd to S and the reaction times (denoted as CS_x , $x = 1, 6, 12, 18, 25, \text{ and } 45$ h). The high-angle annular dark field-scanning transmission electron microscopy (HAADF-STEM) image exhibited a resolved phase junction between the shell and core region, and the stacking mode of the CdS lattice changed from the cubic phase (ABCABC) to the hexagonal phase

(ABABAB) (Fig. 12g). Further stability experiments showed that the hydrogen production of the optimal CdS NRPJs was maintained at a high level after 400 h of irradiation, which was much higher than that of hexagonal CdS (only about 10 h) (Fig. 12h). The stable performance of CdS NRPJs was due to the following: (i) the unique core-shell concentric nanorod geometric structure promoted charge transfer through the passivation of surface states and the enhanced tunneling of charge carriers; (ii) the presence of the ultrathin cubic shell not only passivated the surface state of the hexagonal core but also reduced the recombination of charge carriers *via* enhanced tunneling.

Moreover, although the photogenerated electrons of ZnS with more negative potential is beneficial for the photocatalytic hydrogen evolution reaction, the wide band gap of 3.6 eV greatly limits its light response performance. To solve this problem, it might be a promising strategy to combine wide and narrow bandgap semiconductors to form a solid-solution nanocomposite to obtain a controlled bandgap width through generating new orbital hybridization of atoms. For instance, Hsu and co-workers prepared a $\text{Zn}_{1-x}\text{Cd}_x\text{S}$ solid solution with a zinc blende-wurtzite phase homojunction in between for photocatalytic hydrogen evolution using $\text{Na}_2\text{S}-\text{K}_2\text{SO}_3$ as the electron donor and a 300 W Xe lamp as the light source.¹⁸⁷ In the TEM (HR-TEM) image of $\text{Zn}_{0.52}\text{Cd}_{0.48}\text{S}$, an interplanar spacing of 3.3 Å was close to the value of the zinc blende phase for the $\text{Zn}_{0.52}\text{Cd}_{0.48}\text{S}$ (111) facet and wurtzite for the (002) facet and *d*-spacings of 3.2 and 2.1 Å were respectively matched with the values of the (101) and (220) facets in the wurtzite phase, indicating the possible construction of the heterojunction between these zinc blende and wurtzite phases (Fig. 13a). In zinc blende and wurtzite phases, Zn/Cd atoms attached to four S atoms ($[\text{Zn}/\text{Cd}]_4$) were connected to each other by sharing the corners to construct a three-dimensional structure to form heterojunctions. After visible light irradiation, the CB electrons of the zinc blende phase would transfer to the CB of the wurtzite phase and the VB holes of the wurtzite phase would diffuse into the VB of the zinc blende phase due to Fermi level equilibration. Therefore, the excited CB electrons in the wurtzite phase would participate in the hydrogen evolution reaction and the VB holes in the zinc blende phase would be consumed by the scavenger, resulting in an improved photocatalytic performance toward hydrogen evolution. More importantly, compared with single CdS, the prepared $\text{Zn}_{0.52}\text{Cd}_{0.48}\text{S}$ has fewer Cd-S bonds, which reduced the exposed area of the sample in the electrolyte, resulting in an enhanced photocatalytic stability. More recently, in order to solve the aggregation of Pt cocatalysts, Ng and co-workers prepared twinned $\text{Zn}_{0.5}\text{Cd}_{0.5}\text{S}$ nanocrystals decorated with highly dispersed sub-2 nm Pt for photocatalytic hydrogen evolution with $\text{Na}_2\text{S}-\text{Na}_2\text{SO}_3$ or ascorbic acid as the sacrificial reagent under 500 W Xe arc lamp irradiation (Fig. 13b).¹⁸⁸ Cycling tests showed that the optimal sample (8Pt- $\text{Zn}_{0.5}\text{Cd}_{0.5}\text{S}$) maintained a hydrogen production of 85.0 under alkaline conditions and 80.8% under acidic conditions after five cycles (30 h) (Fig. 13c and d). Also, no obvious difference in morphology and crystallinity of 8Pt- $\text{Zn}_{0.5}\text{Cd}_{0.5}\text{S}$ was found after the reaction, as demonstrated by the TEM and XRD image. The above results all demonstrated that the prepared sample with

zinc blende-wurtzite phase heterojunctions in between could achieve improved activity and stability for photocatalytic hydrogen evolution.

4.5.5. p-n heterojunctions. When a p-type semiconductor and n-type semiconductor are coupled to form a p-n heterojunction, holes are enriched in the p-type side of the coupling interface, while photogenerated electrons are accumulated in the n-type side since the electronic structure of the two semiconductors is different, resulting in band bending and Fermi level equilibration.^{189,190} In this case, electrons and holes have a concentration gradient at the heterojunction interface, accompanied by the formation of a built-in electric field with the same direction of electron transfer, which facilitates the directed transfer of charge carriers between the two semiconductors.^{191,192} Therefore, the construction of a semiconductor-based composite with a p-n junction can also achieve long-term stability. For instance, a Cu_3P/CdS p-n heterojunction with CdS nanorods decorated with Cu_3P was

prepared through a solvothermal process for photocatalytic hydrogen evolution with $Na_2S-Na_2SO_3$ as the electron donor under visible light irradiation.¹⁹³ The prepared Cu_3P/CdS catalyst exhibited a high and stable performance for photocatalytic hydrogen evolution after four cycles, and no difference in the SEM image of Cu_3P/CdS before and after the reaction was found. This excellent stability was attributed to the formation of a p-n heterojunction between Cu_3P and CdS; as a result, the VB holes of CdS would transfer to the VB of Cu_3P , which greatly prevented the hole-induced photocorrosion of CdS.

Moreover, embedding CdS in a 2D p-n junction composed of MoS_2 and N-RGO was proposed to promote the carrier transfer for a better PEC performance and stability (Fig. 13e).¹⁹⁴ Since MoS_2 and CdS shared the same hexagonal crystalline structure, a high-quality and intimate heterojunction grew together on N-RGO sheets. The space charge region created by the p-n junction of $MoS_2/N-RGO$ resulted in effective charge defective layers in MoS_2 and N-RGO. Therefore, the excited electrons and holes

generated in CdS nanorods would transfer to p-type MoS₂ and n-type N-RGO, respectively (Fig. 13f), which improved the efficiency of photocatalytic water splitting and inhibited the hole-induced photocorrosion of CdS (Fig. 13g).

For PEC systems, Zhang *et al.* reported that the CuSbS₂/CdS/Pt p-n heterojunction composite formed by the combination of

a solution-processed CuSbS₂ thin film and thin CdS layer can achieve a stable performance for PEC hydrogen evolution,¹⁹⁵ as demonstrated by a stable cathodic photocurrent under continuous illumination at an applied potential of 0 V *vs.* RHE during the initial 30 min. However, the photocurrent decayed around 15% of the initial value after 1 h, which was probably attributed

Ti(IV)-Ni(II)/Cds	0.35 M Na ₂ S and 0.25 M Na ₂ SO ₃ ; 350 W Xe lamp	—	86.5% (5 cycles)	Holes can be consumed in a timely manner by the hole-cocatalyst Ti(IV)	138
Zn _{1-x} Cd _x S/Cds	0.35 M Na ₂ S and 0.25 M Na ₂ SO ₃ ; 300 W Xe lamp	AQE: 50.1% at 420 nm	100% (100 h)	The localized acceptor states in ZnS promote the VB holes of Cds to ZnS	145
Graphene/Cu ₂ O NWA/Cu mesh	1.0 M Na ₂ SO ₄ ; AM 1.5G	-4.8 mA cm ⁻² at 0 V; ABPE: 3.3%	83% (20 min)	Enhanced charge separation and transfer by graphene	146
			100% (12 h)		149

Table 2 (Contd.)

Electrode configuration	Electrolyte and illumination conditions	AQY STH efficiency	Stability (retained performance)	Note	Ref.
Carbon nanofiber@ZnIn ₂ S ₄	0.35 M Na ₂ S and 0.25 M Na ₂ SO ₃ ; AM 1.5G	AQE: 25.35% at 420 nm; 18.15% at 450 nm; 2.04% at 500 nm		Vector transfer of CB electrons from ZnIn ₂ S ₄ to carbon nanofibers driven by the hierarchical core-shell structure	
C/Cu ₂ ONWAs/Cu mesh	1.0 M Na ₂ SO ₄ ; AM 1.5G	−3.95 mA cm ^{−2} ; STH: 0.56%	80.7% (20 min)	The protective role of the carbon layer	150
Cds@MoS ₂	0.2 M Na ₂ SO ₄ ; 300 W Xe lamp	—	80.2% (12 h)	MoS ₂ shell promotes the transfer of VB holes from Cds to MoS ₂	152
Cds@ZnS	0.1 M Na ₂ SO ₃ and 0.1 M Na ₂ S; 300 W Xe lamp	—	87% (60 h)	Improved VB-hole transfer from Cds to ZnS by the acceptor states of V _{Zn}	153
Cu@Cu ₂ O/ZnO	0.75 M Na ₂ S and 1.05 M Na ₂ SO ₃ ; 300 W Xe lamp	—	100% (8 h)	Cu core was passivated by ZnO nanorods	157
Cds-Ag-TiO ₂	10 mL TEOA and 90 mL DI water; 300 W Xe lamp	—	100% (20 h)	Improve charge separation and transfer by the Schottky junction	161
Cds/BiVO ₄ NWs	20% lactic acid or 1 M Na ₂ SO ₃ ; 300 W Xe lamp	—	83% (5 h)	Z-Scheme charge separation mechanism	164
Cubic or hexagonal Cds phase junction	0.5 M Na ₂ SO ₄ with 20% lactic acid; 300 W Xe lamp	QE: 41.5% at 420 nm	80% (150 h)	The suitable bonding region width can be the shield for the phase junction	170
Hexagonal@cubic Cds phase junction	0.35 M Na ₂ S and 0.25 M Na ₂ SO ₃ ; 300 W Xe lamp	AQE: 43% at 420 nm	100% (400 h)	Cubic Cds shell can passivate the surface state of hexagonal Cds and reduce the recombination of charge carriers <i>via</i> enhanced tunneling	171
Pt-Zn _{0.5} Cd _{0.5} S	0.1 M Na ₂ S and 0.1 M Na ₂ SO ₃ or 0.1 M Na ₂ S/0.15 M ascorbic; 500 W Xe lamp	AQY: 7.15% (0.1 M Na ₂ S/Na ₂ SO ₃); 8.56% (0.15 M ascorbic)	85% (30 h, 0.1 M Na ₂ S/Na ₂ SO ₃); 81% (30 h, 0.15 M ascorbic)	Enhanced spatial charge separation by the synergistic effects of homojunctions and heterojunctions	173
CuSbS ₂ /Cds/Pt	0.5 M Na ₂ SO ₄ ; AM 1.5G	−4.2 mA cm ^{−2} at 0 V	85% (1 h)	The formation of a p-n heterojunction between CuSbS ₂ and Cds	180
BiVO ₄ /FeOOH/NiOOH	V ₂ O ₅ and 1 M borate buffer; AM 1.5G	AM 5.0 mA cm ^{−2} at 1.9 V	100% (60 h)	Controlling the dissolution	190
Pt/Cds@Al ₂ O ₃	0.2 M Na ₂ SO ₄ ; 300 W Xe lamp	AQE: 0.11% at 430 nm	100% (30 h)	Reduced oxygen-induced photocorrosion by the artificial gill	193

to the partial photocorrosion of CdS and the subsequent detachment of the Pt catalyst, but the poor stability can be improved by protective coating using TiO_2 .

As mentioned above, the formation of heterojunctions can effectively inhibit the photocorrosion of semiconductor-based catalysts, and further research should focus on improving and optimizing some heterojunction systems to achieve long-term photostability. Taking the type-I CdS–ZnS heterojunction as an example, both ZnS and CdS can be excited by visible light to generate excited electrons and holes. The VB holes of CdS would transfer to the corresponding VB of ZnS due to the more positive VB potential of CdS. As a result, the photogenerated holes would accumulate in the VB of ZnS, which was to prevent the photocorrosion of CdS by sacrificing the stability of ZnS since the surface sulfur ions of ZnS might be oxidized after long-term illumination.

4.6. Hybridization with conducting polymers

Conducting polymers with high conductivity, stability, good environmental compatibility, flexibility and controllability are emerging as novel functional materials in artificial photo-redox reactions.¹⁹⁶ In particular, due to the excellent conductivity and flexibility of polyaniline (PANI), coating of PANI on the surface of the semiconductor to construct the core–shell structure can greatly improve the stability of the semiconductor.¹⁹⁷ This is attributed to the fact that PANI acts as a physical barrier to prevent direct contact between the semiconductor and the external environment, thereby preventing the dissolution of the semiconductor. In addition, the good conductivity of PANI can promote the transfer of charge carriers at the interface and suppress the photocorrosion caused by the accumulation of photogenerated carriers.¹⁹⁸ For example, PANI@CdS core–shell nanospheres with a PANI thin layer on porous CdS nanospheres were constructed through a proton doped *in situ* polymerization method.¹⁹⁹ XPS analysis of S 2p_{3/2} peaks showed a slight increase in binding energy from 151.9 eV in CdS to 152.7 eV in PANI@CdS, indicating that PANI@CdS exhibited better photocorrosion resistance under light irradiation compared to CdS nanospheres. The cycle experiments showed a stable hydrogen production on PANI@CdS core–shell nanospheres after six cycles, and this excellent stability was attributed to the fact that newly formed C–S or N–Cd bonds greatly prevented the reduction of S^{2-} to S^0 . In another work, as the cycle experiment progressed, the hydrogen evolution rate of single Ta_3N_5 gradually decreased.²⁰⁰ However, no significant decrease in hydrogen evolution of Ta_3N_5 coated with thickness-tunable PANI was detected even after six cycles, which was due to the fact that the PANI shell can effectively prevent the contact between the holes and nitrogen anions in Ta_3N_5 , thereby improving the stability of Ta_3N_5 .

In addition to PANI, the stability of CdS can also be improved by coupling it with the conjugated polymer polyimide (PI); *in situ* XPS analysis suggested that the photogenerated electrons in PI would transfer to CdS and combine with the holes therein under light irradiation, which could effectively suppress hole-induced photocorrosion within CdS.²⁰¹ A further comparative

study showed that both PANI and polypyrrole (PPy) can prevent Ta_3N_5 from self-photocorrosion caused by the oxidation of the nitride of Ta_3N_5 by self-generated holes, while a relative higher photocatalytic water splitting performance was obtained for Ta_3N_5 /PANI due to the higher electric conductivity of PANI than PPy.²⁰² A similar investigation was also reported by Wang *et al.*, where three types of conducting polymers, PANI, PPy and poly(3,4-ethylenedioxythiophene) (PEDOT) were coated on the surface of CdS nanorods to investigate their photocorrosion resistance and photocatalytic hydrogen evolution.²⁰³ The result showed that PANI and PPy shells with abundant N and C atoms can increase the binding energy of Cd and S atoms on the surface of the CdS nanorods, resulting in a relatively stronger driving force for hole transfer from CdS to the polymer. Therefore, the PANI modified PANI@CdS core–shell nanorods exhibited the highest improvement in the hydrogen production rate and photocorrosion resistance in 30 h without deactivation under visible-light irradiation.

4.7. Control of reaction conditions

In general, the photocatalytic performance and stability of semiconductors are also related to the reaction conditions. For instance, a typical pH-dependent semiconductor, CdS, suffered from serious photooxidative dissolution under acidic conditions even without light irradiation, while the photocorrosion and leaching can be effectively inhibited in a high pH solution.²⁰⁴ However, in the case of ZnO, photocorrosion and dissolution occurred regardless of an acidic or alkaline environment.²⁰⁵ Therefore, the optimization of pH should be taken into consideration in various photocatalytic applications to obtain high performance and stability. Similar pH-determined activity also existed in the PEC system, for example, the surface passivation of GaAs by coating with Ga_2O_3 thin films was a viable method to improve its stability due to the fact that Ga_2O_3 can reduce the density of surface states and decrease the surface recombination velocity of minority carriers (holes in n-type GaAs). However, the stability of an amorphous or polycrystalline Ga_2O_3 layer on GaAs largely depended on the pH values of the surrounding environment, which influenced the rate of oxide formation and photoetching. In addition, Sharma investigated the sensitivity of the photocorrosion of GaAs/AlGaAs microstructures with a stack of 30 GaAs quantum well (QW) layers to pH of aqueous solutions ranging between 2.2 and 11.2.²⁰⁶ The photocorrosion rates of microstructures immersed in strong acid (pH 2.2) or alkali (pH 11.2) reached the highest (0.83 nm min^{-1}) due to the solubility of Ga and As oxides (Ga_2O_3 and As_2O_3), while that in near neutral or moderate pH environments were significantly reduced (0.33 nm min^{-1}) due to the accumulation of some photocorrosion products on the surface. Notably, regulating the electrolyte composition and controlling the dissolution during the PEC reaction can also improve the stability of the PEC system, which is becoming an increasingly attractive strategy. For instance, the stability of BiVO_4 photoanodes was greatly improved by simply adding V_2O_5 to the electrolyte, resulting in negligible decrease in the photocurrent for 60 h.²⁰⁷ Conversely, both Bi and V were dissolved in the

electrolyte in the absence of V_2O_5 , as demonstrated by changes in the XRD pattern after the stability test.

At present, the photocorrosion of semiconductor-based catalysts is mainly caused by photogenerated electron/hole-induced redox reactions. However, the effect of newly formed oxygen on the stability of the photocatalytic oxygen evolution reaction also should be considered.²⁰⁸ Moreover, since the dissolved oxygen is about five times higher than that of hydrogen in water, the recombination of hydrogen and oxygen occurs very rapidly on the surface of photocatalysts, which further results in a decrease in oxygen production.²⁰⁹ Generally, there are two strategies to reduce the effects of newly formed oxygen on photocatalytic performance: one is to cover the semiconductor surface with a protective layer to prevent direct contact between the semiconductor and nascent oxygen. For instance, Ning *et al.* decorated the surface of CdS with chemically inert Al_2O_3 to form a CdS@ Al_2O_3 core@shell structure for photocatalytic hydrogen production under 300 W xenon lamp irradiation.²¹⁰ A cycling hydrogen evolution test showed that CdS or CdS–Pt exhibited poor photocatalytic stability due to the rapid recombination of photogenerated electrons and holes, while Pt/CdS@ Al_2O_3 maintained a high and stable hydrogen production after four cycles (Fig. 14a), which was attributed to the use of the Al_2O_3 shell as a stable oxide matrix to protect the embedded CdS particles from photocorrosion. No obvious changes in phase structure and surface microstructures of Pt/CdS@ Al_2O_3 after multi-cycle were found according to XRD and XPS characterization. High-resolution XPS spectra of S 2p showed that the ratio of S^0/S (total) was 2.02% for used CdS while only 1.00% for the used Pt/CdS@ Al_2O_3 catalyst (Fig. 14b), and ICP analysis showed that the concentration of Cd^{2+} increased gradually with the increase of irradiation time for single CdS, while only negligible Cd^{2+} was detected in the Pt/CdS@ Al_2O_3 catalyst system (Fig. 14c), indicating good photocorrosion resistance performance of Pt/CdS@ Al_2O_3 . However, the hydrogen evolution rate of Pt/CdS@ Al_2O_3 exhibited a slight decrease in the fourth cycle, which may be due to the back recombination of hydrogen and oxygen into water or the presence of nascent oxygen. Inspired by the respiratory system of fish, applying artificial gill to photocatalytic overall water splitting can remove neonatally formed O_2 from water, which not only prevented the oxygen-induced photocorrosion but also retarded the reverse reaction of hydrogen and oxygen recombination back to water (Fig. 14d). As demonstrated by the cycling experiments, Pt/CdS@ Al_2O_3 equipped with the artificial gill exhibited a higher performance and enhanced stability for photocatalytic hydrogen evolution after 10 cycles (30 h) (Fig. 14a). Similarly, artificial gill was also applied in Zhen's work, in which a core-shell structured $Ni_2P@CdS$ photocatalyst was prepared through a solvothermal process for photocatalytic water splitting under visible light irradiation without the addition of any sacrificial reagent and noble metal loading.²¹¹ Cycle experiment, XPS analysis of the used sample and ICP results of the Cd^{2+} concentration in the reaction solutions all demonstrated that the photocorrosion of CdS was efficiently inhibited. More importantly, O_2 evolution close to half of H_2 production was achieved in the $10Ni_2P@CdS$ photocatalytic system equipped

with artificial gill, demonstrating that the removal of newly formed O_2 from water can further improve the photocatalytic performance for water splitting (Fig. 14e). Additionally, since the generated peroxide species (H_2O_2) in the photocatalytic system is also not conducive to the stability of CdS, Zhen *et al.* fabricated peroxide decomposing active MnO_2 thin-layer over CdS nanowires and assembled oxygen separation artificial gill to remove nascent formed oxygen in the dispersion (Fig. 14f).²¹² Considering that CdS might be oxidized to $CdSO_4$ by peroxide species, the oxygen generation performance of $20NiSe/MnO_2$ –CdS was much higher than that of $20NiSe/CdS$ in the dark (Fig. 14g), suggesting that the role of the MnO_2 layer over CdS was to decompose hydrogen peroxide in the $NiSe/MnO_2$ –CdS composite, which can also be proved by the UV-Vis absorption spectrum (Fig. 14h). As a result, a high and stable performance in hydrogen evolution was achieved for $20NiSe/MnO_2$ –CdS but a low and gradually decreasing performance for CdS was observed during four cycles (Fig. 14i).

In general, photocatalytic water splitting is considered a promising method for developing clean energy alternatives to fossil fuels. Over the past several decades, a great deal of effort and research have focused on obtaining high photocatalytic performance by promoting the charge separation and transfer within semiconductors and have achieved substantial breakthrough. Nevertheless, the overall photocatalytic performance is still relatively poor due to their intrinsic stability under light irradiation. To overcome this bottleneck, the focus is gradually projecting on how to improve the photoreaction stability of semiconductors. In line with the focus of this section, various feasible strategies implemented to suppress photocorrosion, dissolution and improve the stability of semiconductor-based composites have been comprehensively summarized, which includes nanostructure engineering (crystal structure, morphology and size control), heteroatom doping, heterojunction construction, surface modification (hybridization with cocatalysts, carbon-based materials or conducting polymers), and reaction environment regulation. As shown in Table 2, a series of rational modification strategies developed for promising photocatalysts can achieve improved performance with respect to PC/PEC water splitting.

5. Conclusions and outlooks

5.1. Concluding remarks

Artificial solar energy-driven technology for hydrogen and/or oxygen generation from water splitting has aroused increasing attention in the scientific community, since this process can generate clean and renewable energy that can replace fossil fuels. Currently, various systems for solar-chemical conversion have been developed, among which water splitting using PC and/or PEC technology is the most widely investigated. Considerable previous research is focused on developing various strategies to improve the photocurrent and efficiency of the PC/PEC system, and significant breakthroughs have been made. However, the long-term efficiency of semiconductor-based catalysts is generally low due to the existence of instability under light irradiation, thereby constraining the overall

performance. Therefore, how to improve the stability or durability of semiconductors under light irradiation is a daunting challenge, aimed at obtaining PC/PEC water splitting systems with enhanced activity and stability. In this regard, this is the right and appropriate time to give a comprehensive and state-of-the-art overview with respect to discussing the photocorrosion of photocatalysts and the corresponding measures to improve stability.

In line with the focus of this review, the latest advances in strategies that have been performed to inhibit photocorrosion of semiconductors in PC/PEC water splitting systems are comprehensively outlined. Specifically, this review begins with the discussion of photocorrosion mechanisms of semiconductors under different circumstances. In general, semiconductor photocorrosion is due to the photogenerated electrons and/or holes participating in the self-oxidation and/or reduction of semiconductors rather than water splitting. Taking typical semiconductors (CdS, ZnO and Cu₂O) as examples, the photocorrosion pathway in the presence of photogenerated electrons and/or holes is thoroughly discussed, which provides a fundamental understanding of semiconductor instability under light irradiation. Subsequently, it is well known that the stability of the photocatalyst is an important indicator to determine whether it can be reused in practical applications, which is usually evaluated by successive cycle tests. However, it is not convincing to use the cycle activity as an indicator to evaluate the stability of the catalyst, as other factors may also result in a decrease in photocatalytic performance after multiple recycle tests, such as active site blocking, loss of sample during recycling, adsorption of intermediates, or surface changes. Therefore, the surface morphological/structural characterization of the sample after multiple cycles is critical to further determine the stability of the photocatalyst. In view of this, various feasible characterization methods used to evaluate or confirm the stability of semiconductors are summarized in the following section.

More importantly, a series of strategies applied to overcome the photocorrosion of the semiconductor are systematically elaborated, with the aim to obtain a PC/PEC water splitting system with high activity and long-term stability for practical application. These modifications include (1) increasing the crystallinity of the semiconductor to reduce the number of recombination centers of photogenerated electron-hole pairs; (2) tailoring the particle size to accelerate the separation and transfer of charge carriers; (3) optimizing the structure/morphology of the semiconductor to obtain improved photocorrosion resistance since the surface atom coordination and surface electronic structure of different morphologies are different; (4) doping with heteroatoms to introduce an impurity level into the forbidden band or form a solid solution to improve charge separation efficiency; (5) loading suitable cocatalysts with a larger work function for electron sinks or lowering the overpotential for hole transfer for timely consumption or transfer of undesired charge carriers; (6) coupling with carbon-based materials and/or conducting polymers used as electron acceptors and transporters to promote charge separation; (7) constructing heterojunctions to

accelerate the separation of photogenerated electrons and holes; (8) controlling the reaction conditions to inhibit the photocorrosion caused by the reaction system environment rather than photogenerated carriers. Nevertheless, there is still a long way to go to further optimize the catalytic activity of photocatalysts to achieve large-scale practical applications.

5.2. Fundamental scientific challenges and future outlook

In general, numerous studies have confirmed that rational modifications for semiconductors can be applied to obtain photocatalysts with enhanced activity and stability for PC/PEC water splitting. However, considerable efforts are still needed to further narrow the gap between theoretical efficiency and current achievements, with the aim of addressing many technical challenges in designing the optimal photocatalyst.

First, since the photocorrosion of semiconductors is caused by the undesired redox reactions between photogenerated electrons and/or holes and the semiconductor, the photocorrosion rate is largely dependent on the withdrawal efficiency of electrons/holes, that is, the improvement in the charge transfer rate can result in enhanced stability. In this regard, in-depth investigation of the photocorrosion pathway and mechanism is of great significance for accurately and effectively tackling photoreaction instability issues of semiconductor-based materials. Although considerable studies with regard to investigating the photocorrosion mechanism of Cu₂O in PC/PEC systems have been made, the photocorrosion pathway is still inconsistent, especially for PEC systems. Besides, the currently widely reported hole-induced photooxidation corrosion mechanism cannot explain the decomposition process of CdS-based photocatalysts under non-aqueous conditions. Notably, the influence of reaction conditions on the performance and stability of semiconductor-based materials cannot be neglected. Further investigations on photocatalytic stability should consider by adjusting the pH of the reaction solution and controlling the reaction atmosphere to alleviate the photoinduced dissolution to some extent.

Second, the photoreaction stability of semiconductor-based materials is generally demonstrated by successive recycling experiments combined with morphology, crystal structure, and surface property characterization of used catalysts. However, some photocorrosion that results in a decrease in activity cannot be convincingly reflected by conventional structural characterization such as XRD, SEM and XPS. Therefore, the development of *in situ* monitoring technologies to directly reflect the change of semiconductor materials in the photoreaction process is a promising development direction, but there is still much room for exploration in this direction.

Next, as the photoreaction stability is also determined by the crystal structure, morphology, crystal facet and so on, further efforts and attention should be focused on optimizing individual semiconductors. For instance, the photooxidative etching of Cu₂WS₄ caused by photogenerated holes can be alleviated by decreasing the ratio of the (101)/(001) crystal facets due to the fact that photogenerated electrons and holes tend to accumulate in the (001) and (101) facets, respectively. Therefore,

tailoring the crystal structure to explore the relationship between photocatalytic stability and facet-dependent performance should be taken into consideration since surface adsorption ability, electronic structures and intrinsic carrier dynamics are determined by the crystal structures of the semiconductor. It is worth noting that unlike PC water splitting using powder photocatalysts in a suspension system, PEC water splitting is achieved by loading photocatalysts on a conductive substrate. Therefore, how to prepare a crystal facet oriented photoelectrode for PEC water splitting remains a technical obstacle to be overcome, which requires the facet-oriented photocatalyst to form a good contact interface with the conductive substrate. Although the direct growth of the facet-oriented photocatalyst on the surface of conductive substrates is the most commonly used method, the effects of the components in the growth solution on the durability of the substrates should be taken into consideration.

Also, in terms of practical application, chemical impurities present in the actual water environment may chemically react with the photocatalyst, resulting in a gradual decrease in stability over time. A typical example is the splitting of seawater in metal sulfide systems. The presence of chemical salts and impurities in seawater will contaminate metal sulfide systems and increase the required bias voltage, thereby reducing the efficiency of seawater splitting and limiting long-term stability.

Last but not least, most photocathodes show good stability in acidic electrolytes while photoanodes can stably perform in alkaline electrolytes. Hence, achieving high stability of the photocathode in a strong alkali electrolyte and that of the photoanode in strong acid electrolytes is still an arduous challenge. Besides, how to improve the stability of film-based materials with a rough surface still needs to be investigated in depth. Also, seeking promising materials with strong light absorption and excellent photocorrosion resistance in aqueous media to omit the protective layer is a common goal.
